Another approach was to enter the names of all residents and their vaccination status in a register (as in India) or on cards (as in Zaire), in the expectation that, after the vaccination team had left, health staff could refer to the records and vaccinate those who had been missed. The preparation of such records, however, was exceedingly time-consuming; keeping them up to date proved all but impossible; and the effort required to find and to vaccinate every person who had been missed was prohibitive. All countries which endeavoured to register the names of vaccinated subjects soon abandoned the practice as being impracticable except the United Republic of Tanzania. There, what were called "ten-cell chairmen" prepared a list of all the inhabitants of their assigned area and, when vaccination teams arrived, called individuals forward one by one for vaccination. There were few countries, however, in which political or other organizations could assume such a burden of clerical work, and even in the United Republic of Tanzania the information was not retained as a permanent record.

Sample surveys to assess the status of immunity of selected population groups were undertaken periodically in a number of programmes. Such surveys proved useful for deciding on vaccination strategies for special groups and, on a larger scale, were important when it came to certifying the absence of smallpox. National and other large-scale surveys were performed in western Africa and in India but they proved of little value. National and, in Nigeria, regional surveys, conducted in western Africa in 1969-1970 to measure overall programme performance, revealed problems in some areas, but the information was obtained so long after the campaign had been conducted that the specific causes of the problems could not be identified nor corrective measures taken (see Chapter 17). In India, the forms and assessment methodology used in Afghanistan (see Chapter 14, Plate 14.3) were introduced in some states. It was hoped that health officers responsible for the house-to-house vaccination campaign would identify areas and

populations which had not been well vaccinated and would take corrective action. Although tens of millions of people were examined in the course of assessment exercises, most health officers saw the activity as an end in itself and took no action to correct problems. Large-scale surveys of this kind were gradually abandoned.

Progress in national programmes had traditionally been measured by the numbers of vaccinations reported each year. The data, compiled by administrative units, continued to be collected throughout the course of the programme but varied considerably in quality. In most areas, the vaccinations actually performed were counted, but in some, the numbers reported were equivalent to the assigned goals, while in others, they were estimated on the basis of the quantity of vaccine used. As the programme progressed, these data received less and less attention and greater emphasis was placed on trends in the numbers of reported cases of smallpox. By the early 1970s, data on the numbers of vaccinations reported each year and in each country ceased to be compiled in Geneva and, by the mid-1970s, interest in them was largely confined to the media, which regularly inquired about the numbers of vaccinations being performed. It proved preferable to give the reporters some estimate than to attempt to explain why such data were no longer available.

### *Legislation*

Legislation on smallpox and vaccination existed or was adopted in most countries, but in most instances it proved to be of little benefit other than as an official statement of policy. In the majority of countries, legislation was enacted which called for compulsory vaccination at or shortly after birth, periodic revaccination, and the mandatory isolation of patients; some countries prohibited variolation and required citizens to report cases of smallpox. On the few occasions when action was taken to enforce such laws, the results were poor and often counterproductive. In India, for example, attempts to levy fines on persons who refused to be vaccinated led to protracted proceedings in the courts without any apparent increase in compliance by the general public. The forcible isolation of patients in hospital often caused many families to hide infected household members and impeded effective containment measures.

The prohibition of variolation may have caused some variolators to abandon the practice but in Afghanistan, for example, it resulted in the general public refusing to supply information about them, making it more difficult to identify them and to persuade them to cease their activities.

Other forms of coercion, however, were occasionally needed and effective in special circumstances. For example, in crowded refugee camps, the rule that all persons should be vaccinated before being given food ensured rapid and complete coverage; during containment vaccination, a police presence often discouraged resistance to vaccination; and in Botswana the government's threat to expel a religious group from the country secured cooperation in accepting vaccination when other measures had failed.

### **The Surveillance-Containment Strategy**

The history and rationale of the surveillance-containment strategy have been described earlier, as has its implementation at the global level. At the national level, the foundation for implementing the strategy was the network of reporting posts making up the national reporting system, complemented by mechanisms for the prompt investigation of cases and the containment of outbreaks. The WHO Handbook stressed the importance of establishing or strengthening a reporting network from the inception of each national programme but postulated that, in countries with a high incidence of smallpox, the available resources would not immediately permit the investigation and containment of all outbreaks. Although the Handbook recommended that a reporting system should be established in all countries as soon as possible, it proposed that, in countries reporting more than 5 cases per 100 000 population, case investigation should be limited to major outbreaks and to those in areas in which mass vaccination had been completed. In other countries, all cases were expected to be investigated and containment measures taken. In mid-1967, the data available showed that only 13 of the 31 countries in which smallpox was then endemic had rates of 5 per 100 000 or more, of which 6 were in western Africa (Dahomey (Benin), Mali, Niger, Nigeria, Sierra Leone and Togo), 4 in eastern and southern Africa (Burundi, Uganda, United

Republic of Tanzania, and Zaire) and 3 in Asia (India, Indonesia and Pakistan).

The belief that it would be some time before all reported cases could be investigated and contained rested essentially on 3 premises which, in most of the endemic countries, proved to be incorrect. The first was the notion that the level of vaccinia immunity in the population was universally low, especially in countries with a high smallpox incidence, and that mass vaccination would be necessary before the numbers of cases decreased sufficiently to permit each to be investigated. Overall vaccinia immunity in some countries was indeed low and mass vaccination campaigns did serve to reduce incidence, notably in Afghanistan, Brazil, Ethiopia, Nepal, northern Nigeria and Sierra Leone. In 1967, however, half or more of the population of most countries were found to have vaccination scars, and among these countries were some which reported a substantial proportion of all cases. In India, Indonesia and Pakistan, more than three-quarters were already fully or partially immune because of past disease or prior vaccination. It was found there that the interruption of smallpox transmission was less closely related to an increase in the proportion of the total population with vaccinia immunity than to better reporting and containment measures. The second misconception was that, where smallpox incidence was high, cases would be so numerous and widely scattered that a great many teams would be required to investigate and contain the outbreaks. With few exceptions, it was discovered that smallpox cases, although far more numerous than reported, were clustered in comparatively small areas, so that relatively few surveillance teams were needed to investigate and contain them. Finally, it was believed that, in most countries, health units were so few and so scattered that reporting systems would have to be based primarily on reports from village leaders, teachers and the like, and that these systems would require considerable time and substantial manpower to establish. In fact, most countries, even many of the least developed in Africa, had a remarkably extensive network of health posts and far larger numbers of health personnel than the WHO Smallpox Eradication unit had expected.

Soon after the Intensified Programme began, it became apparent that surveillance-containment programmes could be developed reasonably quickly and that such systems

could rapidly interrupt transmission. The findings in East and West Pakistan in the years 1965-1968, in eastern Nigeria in 1967 and in Tamil Nadu State (India) in 1968 showed that:

(1) The reporting of cases, although incomplete, was usually adequate to identify most large outbreaks; many other cases could be readily discovered by a few field teams through the investigation of reported cases and by questioning health staff and villagers.

(2) Patients with smallpox usually transmitted the disease to very few people and only to those in close face-to-face contact. Transmission in markets or schools, for example, was uncommon. Outbreaks therefore tended to be clustered among acquaintances in certain parts of a city or areas of the country rather than being widely and randomly dispersed.

(3) Only persons with a rash were able to transmit infection to others; this made it comparatively simple to trace the chain of transmission from person to person.

(4) Where, as was the case in most countries, there was significant seasonal fluctuation in smallpox incidence, few persons or villages were infected during the season when transmission was at a low level; the discovery and containment of outbreaks during this season substantially reduced the number of cases in the subsequent smallpox season.

(5) Outbreaks could be easily and rapidly contained in most areas with a high degree of success by isolating the patient and vaccinating contacts and most persons in the immediate vicinity.

Given also that smallpox was so distinctive that it could be diagnosed reasonably accurately by villagers themselves, that there was an incubation period of fully 10-12 days between cases, and that the vaccine provided more durable protection than had been believed, the conditions for an effective surveillance-containment programme were unusually favourable.

Nevertheless, however logical and attractive the surveillance-containment strategy appeared to be, it was not readily accepted by programme directors. In part, the difficulty lay in understanding and accepting what seemed to be a simple concept—that all cases of smallpox were links in an identifiable continuing chain of infection and that, in every area, there was a finite, usually small

WHO: N. WILLIARD

**Plate 10.28.** Careful questioning of villagers could usually reveal the source of infection of the first case in an outbreak of smallpox, but it was not always easy to tell from their directions where and how far away the person concerned might be.

number of chains. If a 2-week interval between cases is assumed, a single chain of transmission in a country would result in not less than 25-50 related cases in the course of a year. Even in countries with many cases, the number of chains of infection would not be large; a country with 500 cases a year would have no more than 10-20 such chains. Because the cases were so closely related to one another, the strategy required not only the containment of each outbreak but also the discovery of the antecedent cases and outbreaks in the chain and their containment. The lack of comprehension of this principle during the early years of the programme was indicated by the frequent reference by many programme directors to the occurrence of "sporadic" cases rather than to cases whose source of infection could not be found.

At the outset it was difficult to convince the authorities of the usefulness of setting up surveillance teams staffed by competent senior health personnel, although many created "fire-fighting teams" of poorly supervised vaccinators whose task was to adminis-

ter vaccine when epidemics were discovered. Even when demonstration programmes were conducted by its most enthusiastic proponents, the surveillance-containment strategy was slow to gain acceptance. In western and central Africa, Dr William Foege and his colleagues tried to introduce it from the summer of 1968 but, as is recounted in Chapter 17, northern Nigeria, the most heavily infected area, did not participate. In 1968 and 1969, Dr A. R. Rao enthusiastically described his successful experience in interrupting transmission in Tamil Nadu State (see Chapter 15), but he did not succeed in persuading other state programme directors in India to follow his example; in Brazil, the achievements in 1969 of Dr Ciro de Quadros and his colleagues were likewise disregarded (see Chapter 12). Precisely when country-wide surveillance-containment programmes were fully implemented is difficult to say, but approximations are possible for the most populous countries. In the endemic countries, the first were those in western and central Africa, which began late in 1968. These were followed by Afghanistan and Indonesia in 1969, East Pakistan in 1970, Brazil, Ethiopia and Zaire in 1971, Botswana and the Sudan in 1972, India, Nepal and Pakistan in 1973, and Somalia in 1977.

Before 1973, simple surveillance-containment measures were employed, and these are described first in the following sections. From 1973 onwards, with global eradication closer and more resources available, the techniques became increasingly sophisticated; that period is discussed later in this chapter.

#### *Routine notification of cases*

The foundation of the surveillance system was a weekly report from each health unit which documented the number of smallpox cases seen that week; if none was found, a report showing "nil" had to be sent. To simplify and encourage reporting, only the most basic facts about the patients were requested: name, age, sex, village (or urban district), date of onset of rash, and whether the patient had previously been successfully vaccinated (as shown by the presence of a scar). The information could be contained in one line on a form and the report was therefore termed a "line listing of cases". These reports were to be dispatched at the end of the week to an intermediate administrative

unit (a state or province in smaller countries, a district in larger ones) and so on up the echelons, eventually reaching the national programme office. Each week, the national office reported to WHO Headquarters by telex or by mail the number of cases of smallpox by week of report and by district and state or province.

The system was designed to provide only the information that was relevant to programme operation at each administrative level. To check that the system was operating correctly, all units at each administrative level were expected to submit a report whether or not cases of smallpox had been detected. Numbers of deaths were not requested because progress in the programme was monitored in terms of smallpox incidence; the action to be taken, such as investigation and containment, was related to the occurrence of cases rather than of deaths. The information provided by the line listing, which was necessary for the investigation of cases by the surveillance teams, was of the greatest value at state or provincial offices in smaller countries or district offices in the larger ones. To facilitate the transmission of data by telegram or telex, higher-level administrative authorities received current data only on the numbers of cases by administrative unit. More detailed epidemiological information was usually collected and analysed nationally, but at a later stage.

In the notification system, all cases, irrespective of date of onset, were supposed to be recorded according to the week in which they were detected. In most countries, this meant the week in which they were seen by the health unit. A record system of this type was simple to operate and worked far better than one in which an attempt was made to record and tabulate all cases according to week of onset of illness.

In 1967, reporting practices varied widely from country to country; none followed precisely the pattern described above, but many had a reporting structure by which each health unit provided some sort of report weekly or monthly. This often entailed notifying cases of 25-50 diseases together with a variety of data on the operations of the health units. The reports were seldom used for operational or supervisory purposes and efforts were rarely made to ensure that they were submitted promptly or even that all units reported. At intermediate administrative levels, the situation was little different.

Special notification systems were sometimes prescribed for the diseases subject to international quarantine regulations, such as smallpox. Some required village leaders and others who became aware of a case of the disease to report it to the responsible administrative authorities, but this was seldom done. Telex or telephone notification of the quarantinable diseases to national or provincial authorities was also requested in some countries but, again, not consistently carried out. With smallpox, there were other problems. Some health units diagnosed mild cases as "variola minor", considering them not to be "true smallpox", and did not report them. Where, as in India, the occurrence of cases was taken as evidence by supervisors that the vaccination campaign had been inadequate, health units suppressed reports of cases. In all countries, there was such substantial underreporting that it is not surprising that many countries believed smallpox to be a much less serious problem than it was.

The development of fully satisfactory notification networks took not less than 1-2 years. In many countries, this was facilitated by epidemiologists or mobile surveillance teams, each of which could usually cover an administrative area with a population of 5-10 million. The teams regularly visited each health unit to explain the programme, emphasize the need to report cases, encourage vaccination, distribute forms and vaccine, and check on late reporting. When cases were reported, the team investigated and contained the outbreaks, sometimes with the help of those at the health unit, and usually discovered many additional cases in the process. The frequent visits to the health units by the mobile teams and their prompt response when cases were reported proved to be a great stimulus to reporting, especially because other supervisory health staff rarely visited health units. Interest was also stimulated by national surveillance reports, published weekly or monthly in many countries and distributed to health staff at all levels.

Of the many problems encountered in developing the notification network, two deserve mention because of their relevance to the development of systems for other diseases. The first was the difficulty of persuading health authorities of the need to receive regular weekly reports, even when no cases were found. Most assumed that if no report was received, no cases had been detected. Experience showed, however, that the units

that failed to submit reports were usually the least effective in performing functions of all types, including vaccination. It was in such areas that large, hitherto unknown epidemics were the most frequently discovered. The second problem, encountered only in India, related to the decision by government authorities to record all cases according to week of onset rather than week of report. This resulted in chaotic record-keeping at all levels of the health system and contributed to a significant underreporting of cases (see Chapter 15).

Reporting units, even in the smallest countries, numbered 100 or more, and in countries with large populations, more than 1000. In India, the largest of the endemic countries, there were no fewer than 8167 units reporting weekly to 397 district offices, which, in turn, reported to 31 state programme offices, and these to the national programme office in New Delhi.

#### *Other mechanisms for case detection*

Routine case notification by health units, however assiduous, provided only incomplete data on numbers of cases. While such data were useful when deciding on the allocation of resources and as a point of departure for field investigations, additional measures were required to detect most and eventually all existing cases. For various reasons, patients did not always go to health units: some lived too far away; many, especially with variola minor, were not sufficiently ill to seek medical attention; some believed, rightly, that therapy would be of little value; and some wished to avoid detection so as to escape, for religious or cultural reasons, compulsory hospitalization or vaccination of household contacts. Not surprisingly, few patients came to health units in areas in which their dwellings were burnt as a prophylactic measure.

Help in detecting cases was sought from other health staff as well as from the government and private individuals. Health workers who moved from village to village in the course of family planning, malaria, leprosy or yaws control programmes should have been a useful source of information, but few contributed significantly until a reward was offered for detecting cases of smallpox. At different times and in different countries, appeals to report suspected smallpox cases were also made to administrative officials,

religious leaders, development officers, agricultural extension workers and police and security forces; although many were helpful in other ways, their assistance in reporting on smallpox was minimal.

The most effective mechanism for detecting cases not seen at health units was the field investigation of the cases which had been reported. This was usually one of the first measures to be undertaken as surveillance programmes developed. Because the spread of smallpox tended to be limited to close personal contacts, many additional cases could usually be quickly discovered among the family and village or neighbourhood contacts of a case. By careful questioning of the patients, sources of infection in other villages could be identified and investigated. In Brazil, for example, the investigation of each reported case brought to light an average of 50 other cases.

As the Intensified Smallpox Eradication Programme progressed, it became apparent that the discovery of cases through routine reporting and the investigation of outbreaks were still inadequate. Many outbreaks were large by the time they were found and had already spread to other areas. Monthly or semi-monthly visits to all villages would have served to detect cases earlier, but in most countries it would have taken a year or more to visit every village, even briefly, given the number of the smallpox eradication staff.

Methods were therefore required to permit the staff to search rapidly for cases over wide areas. Among the first of the methods developed were inquiries by workers in schools and markets. Schoolchildren proved to be an exceptionally good source of information, being well informed as to who in their villages was ill and with what diseases and tending to be more forthcoming with information than adults. Surveillance teams were able, in a brief visit to a school, to question children from villages as distant as 5-10 kilometres. This approach, developed in Indonesia in 1969 (see Chapter 13), eventually became standard practice in all surveillance programmes. Akin to this approach was the questioning of those attending weekly markets.

When the numbers of outbreaks in a country or area decreased to very low levels, it became possible to search for cases among those who had been exposed to patients but had left the area. Tracing such contacts was difficult and not especially productive: com-

paratively few contacts became ill, since many were already immune or had not been sufficiently exposed to become infected. This technique was seldom used, therefore, even when there were few outbreaks.

The techniques for case detection described above were adequate for programmes in most countries of Africa and South America as well as some in Asia, but in the densely populated areas of Asia additional measures were adopted. Village-by-village and even house-to-house search became possible when additional staff could be recruited. The first village-by-village search was conducted in Indonesia in 1969 and the technique was employed thereafter in high-risk areas (see Chapter 13). It began to be used in India in 1972 and was extended nationally in 1973 (see Chapter 15). It then became the standard practice in the remaining endemic countries.

#### *Data analysis and surveillance reports*

Important elements of the surveillance process, as described in the WHO Handbook, were "the concurrent analysis and interpretation of reported data and studies" and the "widespread dissemination of the compiled and interpreted data to principal reporting sources and to others concerned with disease control activities". Although such activities might appear to be logical and routine in any systematic data collection process, they were uncommon at first in the endemic countries. This reflected, in part, the fact that progress in smallpox programmes had been measured by numbers of reported vaccinations rather than by numbers of cases of smallpox, and, in part, the disdain commonly felt by health officials for routinely collected morbidity data, which are everywhere recognized to be incomplete. Rather than using the information that was available, while at the same time trying to improve the system, such officials took little notice of the data.

Routinely collected morbidity data, incomplete and biased though they may have been, proved of value from the beginning of the programme and, as they improved, became ever more useful. Vaccination campaigns in most countries began in the areas that reported the largest number of cases and, in some, smallpox was eliminated before the national campaign came to an end. When cases were found primarily among children less than 15 years of age, the campaign

strategy was altered to focus particularly on the vaccination of children. The early observation that most cases of smallpox occurred among persons who had never been vaccinated led to the studies previously mentioned which showed that vaccinal immunity was far more long-lasting than had been appreciated and to a consequent emphasis on primary vaccination. Many other illustrations of the usefulness of morbidity data could be offered.

In addition to the international surveillance reports, already described, national surveillance reports were also prepared and had a major impact on the various programmes. The first of these was a weekly mimeographed report, which was started in Brazil in 1967 (see Chapter 12). When special surveillance teams began discovering large numbers of unreported cases, it described what appeared to be a developing epidemic and this in turn attracted the attention of the press together with renewed political commitment and increased resources.

#### *Containment*

The containment of an outbreak was, in principle, straightforward, calling for isolation of the patient, vaccination of the members of his household and other contacts, investigations to determine if there were other cases in the area and identification of the source of the outbreak so that it, too, could be investigated and contained.

Before 1967, the responsibility for, and the methods used in, investigating and containing outbreaks differed from country to country. In most, local health officers were expected to initiate the necessary control measures, although national vaccination teams were sometimes deployed. Where variola major was present, mass vaccination was widely used when large outbreaks occurred, but smaller outbreaks were usually ignored. Special measures were seldom taken against the mild variola minor form. Patients usually remained in their homes or, where hospitals existed, were confined to a smallpox ward or a general infectious diseases ward. Special investigations to identify all cases or to determine the source of infection were practically unknown. If the patient recovered, it was sometimes the practice to disinfect surfaces in the room by scrubbing them with a formalin solution or carbolic soap and to burn the patient's clothing and bedding. In some places the practice was to

**Plate 10.29.** Front of the WHO smallpox recognition card that was widely used from 1971 in endemic countries. Smallpox eradication workers searching for cases would show the card and inquire whether anyone had seen a person with a similar rash.

**Plate 10.30.** Reverse of the WHO smallpox recognition card. It was on heavy-duty A4-size paper and cased in plastic for protection, unlike the pocket-sized version shown in Plate 10.11. In Ethiopia, a variant was used that showed an Ethiopian patient with *variola minor*.

**Plate 10.31.** Schoolchildren in Somalia (A) and in India (B) are shown the WHO smallpox recognition card and asked if they know of cases. Information about possible cases within a radius of 10 kilometres or more was frequently obtained in this way.

burn all dwellings in which cases had occurred.

The WHO Handbook devoted only 7 pages to a discussion of proposed containment and disinfection methods; the latter, quoted from Dixon (1962), were impracticable and, indeed, scientifically questionable. For example: "Letters: (a) Iron separate pages, both sides; (b) Expose loose pages and envelope to formalin vapour for three hours, then seal." The Handbook recommended that, in countries reporting fewer than 5 cases per 100 000 population, responsibility for containment should be given to a "knowledgeable person", defined as a trained epidemiologist. It recommended that the patient should be isolated, the source of infection identified, and household contacts vaccinated as well as "several hundred to several thousand persons ... in a brief intensive effort". It had little to say about the practical problems of containment, since there was little information in the published literature and those responsible for writing it had no practical experience of their own.

The diligence with which the containment of outbreaks was pursued after 1967 paralleled, in general, the development of reporting systems. Experience in executing containment measures gradually accrued as the programme progressed, but up to the end of 1973 the measures taken were comparatively simple ones, quite different from the disci-

plined methodology which began to be applied during the concluding stages of the programme in Asia and Africa in 1974.

Field experience showed that the isolation of patients in their own home or in a separate dwelling was usually the best practice. Because there was no effective therapy for smallpox, the hospitalization of patients was of little benefit. Moreover, hospitalized patients frequently spread infection to other patients, visitors and staff because hospital administrations regularly ignored isolation procedures. In fact, the authors are unaware of any institution in any endemic country, except one hospital in Madras (India), in which proper isolation practices were followed until they were introduced by smallpox eradication programme staff. So prevalent was the problem that programme staff often referred to hospitals as "smallpox transmission hospitals". Precautionary procedures were comparatively simple—the vaccination of staff and visitors, the isolation of all smallpox patients in a special ward and the vaccination of all such patients to protect any who might have been misdiagnosed. In most hospitals, however, smallpox patients were regularly accommodated in infectious disease wards with patients with other diseases or, at best, intermingled with chickenpox patients. Visitors usually came and went as they pleased and hospital staff themselves were frequently unvaccinated. Even late in the course of

**Plate 10.32.** Search workers used loud hailer at weekly markets, such as this one in Ethiopia, to seek information about possible cases of smallpox.

national programmes, infection in hospitals continued to occur, the last cases in Brazil and South Africa, for example, having been infected in this way. Indeed, the last case of endemic smallpox, in 1977, was in an unvaccinated hospital employee.

In most countries, the isolation of the patient in his home was both traditional and satisfactory but, in some, social customs led to the infection of many susceptible persons. Among some groups in the Indian subcontinent, for example, it was traditional for relatives and friends to visit those who were very sick, and in Indonesia young children with smallpox were often carried from house to house to be seen and comforted by relatives. Not surprisingly, simple containment measures were ineffective in these areas and smallpox spread rapidly. Interestingly, the most effective practices of patient isolation were found among scattered, illiterate African and Asian tribal peoples, who often arranged for the patient to be housed in a separate dwelling and to be cared for by someone who had previously had smallpox.

Special disinfection procedures after the patient had recovered were uncommon except for boiling or burning the patient's clothing and bedding; hospital rooms were cleaned in the ordinary way. Because few cases appeared to result from contact with fomites, no attempt was made during the programme to alter customary disinfection methods whatever they were.

The vaccination of contacts and the "several hundred to several thousand persons" in the area was fairly perfunctory until the programme was greatly intensified in 1974. Such vaccination was usually conducted during the main part of the day in the course of outbreak investigation. Inevitably, a number of residents, including household contacts, were away from home or their village at this time and so remained unvaccinated. Nevertheless, in Africa and South America, this brief but incomplete vaccination effort was usually sufficient to contain the outbreak eventually, even though one or several generations of cases might subsequently occur. In some countries, as cases became fewer, teams began to vaccinate early in the morning and in the evening to ensure more complete coverage, but seldom was a systematic effort made to enumerate and vaccinate all residents.

Attempts to trace the source of infection were sometimes made but were not always successful, special skills and diligence being required in questioning the patient, his family and friends. It was especially difficult to obtain such information, for example, from persons engaged in illicit activities such as smuggling or from people who had acquired the disease from prostitutes. A few programme staff, however, acquired an unusual mastery of the technique of tracing sources of infection and prided themselves on being able to identify the source of every

outbreak. Conversely, there were some other-wise competent epidemiologists who were consistently unsuccessful in this task; a few, especially early in the programme, simply characterized most cases as "sporadic".

### Surveillance and Containment Measures after September 1973

From September 1973, the nature of surveillance and later of containment measures began to change significantly. By then, comparatively simple surveillance-containment operations and mass vaccination campaigns had been successful in stopping transmission in all but 5 countries—Bangladesh, Ethiopia, India, Nepal and Pakistan. Even in these countries, simple surveillance-containment measures had successfully eliminated smallpox from large areas, including much of southern India, Nepal and Bangladesh. Lack of progress in northern India and Pakistan, however, made it clear that neither country was likely to stop transmission without a more concerted effort. In the summer of 1973, therefore, a more elaborate system for case detection and subsequently for containment was devised by WHO and Indian staff which would involve large numbers of health service personnel, larger numbers of WHO and Indian epidemiologists, and greater financial support. Similar intensified efforts began late in 1973 in Pakistan, early in 1975 in Bangladesh, towards the end of 1975 in Ethiopia, and in May 1977 in Somalia when smallpox again became endemic there following importations.

#### *Surveillance*

In India, the persistence of smallpox despite high levels of vaccinal immunity was attributed partly to the high population density and partly to the frequent suppression of reports of cases by health staff. When, in 1974, the sources of all outbreaks began to be more carefully investigated, it became apparent that there was a third factor of significance—the frequent spread of smallpox over long distances. Of 6227 outbreaks for which the source was identified in 1974-1975, 1129 (18%) were found to have originated outside the state in which the outbreak had occurred and 25 outside the country itself (Basu et al., 1979). By comparison, data from Ethiopia,

fairly typical of the experience in Africa, showed that the source of only 2% of outbreaks was outside the region (province) concerned (Tekeste et al., 1984).

It was believed that the key to eradication in the remaining affected areas was the more complete and the more prompt detection of outbreaks. Accordingly, it was decided to supplement the routine notification system by enlisting the participation of health staff from other programmes in national village-by-village, and eventually house-to-house, searches. Such searches had been shown to be effective in a district and in one state of India during 1972-1973 and, since large numbers of health staff were available in that country, it seemed reasonable to try to undertake them on a national scale. A detailed plan and guide were prepared which called for every inhabited locality in the search area to be visited in order to detect cases or to confirm their absence. In concept the plan was simple. The health staff in each administrative area would each be assigned 1-3 villages to visit each day. With the numbers available, an entire state could be covered within 7-10 days. After the search, the staff of the smallpox eradication programme, assisted by the local health workers, would contain the outbreaks which had been detected.

This proved to be feasible in Pakistan and Bangladesh as well as in India, but in Ethiopia and Somalia, with few health staff, temporary workers were required. Those from local ethnic groups, even the illiterate, who knew the topography and the people, proved to be the most effective—indeed, better than educated persons from urban areas. Considerable numbers were involved in each national search—more than 120 000 in India, 10 000-20 000 each in Bangladesh and Pakistan, and several thousands in Ethiopia and Somalia.

Training and motivating the large numbers of people involved were easier than had been expected. Training sessions of 1-2 days' duration were conducted before each search for personnel at the highest and intermediate administrative levels; subsequent sessions were conducted by intermediate-level supervisors for primary health centre supervisors, and, finally, by these supervisors for all health centre staff. Each intermediate and lower-level supervisor thus attended 2 training sessions, one as a participant and one as an instructor. At each meeting, the method of search was described

and, before the second and subsequent searches, the results and problems of the previous search were reviewed. The forms used were so designed that, when properly filled out, they guided each supervisor and search worker in carrying out his responsibilities.

The searches were conducted at different intervals in different areas—usually once every 4–8 weeks in endemic areas and once every 2–3 months in non-endemic areas. In the interval, additional search programmes were carried out in high-risk areas and in areas in which performance had been poor.

The development of a local search plan, in an area with perhaps 100 000–200 000 inhabitants, was the responsibility of the health officer in charge of that area. He selected the personnel to be employed and, using maps and demographic data, gave each worker 1–3 villages to visit each day on certain specified days. Those conducting the search travelled on foot or by bicycle. Some overlap in the sectors assigned helped to ensure that no areas were omitted. Usually, the workers travelled alone but in geographically difficult or dangerous areas a 2-man search team was used. A supervisor oversaw the work of 5–10 workers.

Through 1974, searches were conducted only in India and Pakistan and, until the autumn of that year, search workers were instructed to contact a number of different persons and groups in each village: the administrative head, postman, watchman and

other local figures; people working in health units; children and teachers in schools; owners and customers of tea-shops; frequenters of markets; and persons at temples, mosques, churches, bus stops and similar places where people gathered in large numbers. The inhabitants of clusters of houses in each of 4 sectors of a village were to be visited, as were those in the poorest area. Although the more diligent workers were able to carry out all these activities, many did so perfunctorily, with the result that a number of cases failed to be detected. Overall assessment of the activities proved difficult, as did the identification of those performing inadequately. In the autumn of 1974, the numbers of cases and outbreaks had decreased sufficiently so that the method of search could be changed to one of house-to-house visits. A reward was offered and each search worker was required to place a poster or to paint a notice publicizing the reward on every tenth house, as well as on the schoolhouse. The quantity of forms, reports and posters required for each national search was considerable, one estimate in India indicating the need for a total of 8 tonnes of paper.

To ensure that the proper questions were asked, each search worker was trained to use a particular approach: he was to introduce himself as a health worker, explain the reason for his visit, show the WHO smallpox recognition card, inquire about suspected smallpox cases and tell the people about the reward and where to report suspected cases.

When a suspected case of smallpox was found, the search worker immediately notified his supervisor or the nearest health unit so that a containment team could begin work. In Ethiopia and Somalia, in which the population was widely scattered, search workers usually carried vaccine and were instructed to begin containment vaccination when a suspected case was found. The periodic discovery of suspected cases was important in sustaining the interest of the workers, but in areas which had become smallpox-free, interest was sustained and a mechanism of assessment provided by requiring them also to look for cases of chickenpox and measles and to detect and report all deaths accompanied by skin rash. This also provided added assurance that smallpox had not returned.

Special searches had to be devised for Somalia and other areas such as the Ogaden desert in which groups of nomads were

continually on the move. As is described in Chapter 22, different approaches were used to ensure the coverage of large areas while at the same time ensuring adequate supervision and assessment. In these areas, teams of 2 regularly walked long distances—50–150 kilometres—usually carrying vaccine so as to vaccinate any nomads encountered.

The organization of searches in urban areas was complex, and ingenuity was needed to coordinate the activities of the many and varied groups who usually participated, including numerous categories of municipal health staff and sometimes medical students, trainee nurses and volunteers from public services.

An intensive publicity campaign before and during the search, including the use of loudspeakers on cars and rickshaws, slides for projection, radio announcements, newspaper articles, handbills and posters, was found to be important in obtaining cooperation. As in rural areas, house-to-house searches were conducted, but schools, markets, factories and private medical practitioners were also visited. Special attention was given to areas in which migrants lived and to poor neighbourhoods. In urban areas, it was found that a search worker could visit 150 houses a day or about 1000 houses a week; 10 search workers with 2 supervisors were required to search an urban area with a population of 150 000.

Continuing assessment of search operations was as important as independent assessment of mass vaccination campaigns, as became apparent after the first search in India. Supervisors reported that 90% of villages had been searched and, indeed, thousands of previously unreported cases were detected, but a separate assessment by surveillance teams discovered that less than half the total had, in fact, been covered. An assessment programme was therefore developed which provided for independent appraisal of 5–20% of the localities by higher-level health officials and special teams. Where it was found that less than 85% of villages or urban sectors in an area had been searched, the entire search process was repeated in that area. As time passed, the minimum standard was raised to 90% and the areas chosen for assessment were deliberately selected to include those least likely to have been well covered, such as the villages furthest from health units and those with a high proportion of migrants or very poor populations. Similar approaches were adopted for assessment in the other countries.

The initial assessments were comparatively simple to make, being based on the statement of the village leader or the villagers themselves that a search worker had been in the area and the finding of a smallpox poster or marking on a wall (Plate 10.35). More sophisticated assessment became possible when house-to-house searches began and a reward was offered. Individual households were then asked whether they had been visited by a search worker, whether they knew the amount of the reward and whether they knew where to report cases of smallpox. Later, when workers endeavoured to detect cases of measles, chickenpox and other

WHO / P. ROBERTS

illnesses with rash, the incidence of these diseases in different areas was compared and those in which few such cases were reported were searched again by special teams.

Assessment itself involved large numbers of people. In India, for example, 3 million households in 107 000 villages were routinely visited following each search. The numbers were smaller in Somalia, but finding the scattered villages and nomad camps made the task no less challenging.

The value of assessment in the search programme suggested its possible use for other purposes; this was demonstrated in Bangladesh (Joarder et al., 1980), in which teams also evaluated the availability and utilization of tube-wells in rural areas, contraceptive pills (and public awareness of family planning methods), and rural health centres. In other areas, data regarding the occurrence of measles, tetanus, poliomyelitis and blindness were obtained.

Surveillance teams were especially important in the planning and assessment of the search programmes and in other types of search procedure. Until 1973, there had been few of them in Asia, and they had been inadequately supervised and primarily responsible to state or district authorities; from 1973 to 1975, their numbers grew rapidly, proportionately more being assigned to areas in which smallpox was endemic. Those responsible for surveillance over the largest

contacted. The cards were subsequently useful in assessing the efficacy of search among nomads.

Special search programmes were required for areas especially difficult of access. Each country had a number of such areas, usually with a small, widely dispersed population and few health services, where teams often had to travel by boat, horse or camel or to walk for one or more weeks. Where *variola major* had been present, as in Asia, it was possible through facial pockmark surveys to determine the recent past history of smallpox. Such surveys in Bangladesh, India, Pakistan and Nepal during 1975–1976 revealed only a few small outbreaks which had occurred earlier but not been reported (Ježek & Kanth, 1978; Nair, 1978; Basu et al., 1979; Ježek et al., 1978b; Joarder et al., 1980). This was partly because of infrequent contact between the inhabitants of these isolated areas and those of the more populated endemic areas and partly because of the traditional practice of isolating patients that was followed by many tribal peoples.

The remote areas of Ethiopia and Somalia presented a different challenge. *Variola mi-*

*nor* had been present in these areas during recent decades, rarely leaving persistent facial pockmarks. Because the disease was mild, patients were usually not isolated and smallpox persisted for long periods. Repeated searches were required to confirm the absence of smallpox, and these were conducted in many areas of both Ethiopia and Somalia as well as in the southern Sudan (WHO/SE/74.67, Bassett et al.; Foster et al., 1978; Ježek et al., 1981; Tekeste et al., 1984).

Ultimately, the most effective method of ensuring prompt reporting proved to be to offer a reward. This had first been done in Indonesia in 1972, when a large outbreak was discovered in what was thought to be a smallpox-free area of Java (see Chapter 13). Numerous illnesses with rash were reported but none proved to be smallpox. Later that year the practice was adopted in Karnataka State in India, and soon thereafter in several southern states of that country, all of which were free or virtually free of smallpox. The rewards ranged from 10 to 25 rupees (US\$1.30–3.25). The practice of offering a reward was slow to be adopted more widely, however, because many national and state

officials feared that it would establish a precedent whereby a reward would be expected for the report of any illness. This fear proved to be unfounded.

At the beginning of 1974, most Indian states sanctioned a reward of 50 rupees (US\$6.25), rising to 100 rupees (US\$12.50) at the end of 1974 and to 1000 rupees (US\$125) in July 1975, shortly after the occurrence of the last case. The offer of even larger sums was considered but programme staff believed that too large a reward would cease to be credible. Even the amounts mentioned represented scarcely believable sums in a country in which workers were sometimes paid 10 rupees or less per day. Initially, the rewards were not well publicized by the health workers, who wished to keep them themselves; but the problem was resolved by offering 2 rewards, one for the person who reported the case and the other for the health worker who investigated it. Only 2 countries besides India offered a reward while cases were still known to be occurring: Bangladesh in mid-1974 and Somalia in April 1977. In Bangladesh, 220 000 takas (US\$27 280) were paid in all, a modest sum for the improvement in reporting which occurred. The total expenditure in rewards is not known for India or Somalia, but it is believed to have been substantially less than in Bangladesh.

Rewards were also offered in other countries after they became free of smallpox but, although many suspected cases were reported, none was confirmed. Finally, in 1978, the World Health Organization offered a reward of US\$1000 for the reporting of a case that could be confirmed; this, too, brought to light a great many suspected cases with rash due to many different causes. Although none proved to be smallpox, the offer of the reward was of value in confirming that eradication had been achieved.

Many approaches were used to publicize the reward but studies showed that the most

effective was simply for search workers and surveillance teams to talk to the people. In surveys in both urban and rural areas of India, 70-85% reported that they had learned about the reward from a search worker; even higher figures were recorded in Somalia.

In 1975, when smallpox incidence had decreased to very low levels, other techniques were used in case detection. Health centres and hospitals were asked to enter the names and addresses of all suspected cases in a "rumour register" so as to obtain a record of such cases which could later be checked by surveillance teams; specimens were taken in increasing numbers from patients with chickenpox in order to ensure that errors in diagnosis were not being made; and surveys were conducted over wide areas to detect persons with facial pockmarks in order to determine whether any had had smallpox after transmission had apparently been interrupted. These activities continued throughout the certification period and were among the important steps taken to certify that transmission had been interrupted (see Chapter 24).

Of the many methods used to detect cases after 1973, in India house-to-house search was clearly of the greatest importance, followed by field investigations of the cases detected (Table 10.11). In Somalia, however, reports from the public in response to the offer of the reward previously mentioned were more important, that offer having begun to be publicized in April 1977 before house-to-house searches had been organized. Because of the reward, young nomads found it profitable to search widely for cases and many reports were received from them.

#### *Containment measures after September 1973*

In the change of strategy which began in the autumn of 1973, the initial concern was to ensure the prompt and more complete

**Plate 10.38.** A sketch map of an infected village, prepared for containment activities in Bangladesh. All the houses were numbered; arrows indicated the order in which the houses were to be searched.

detection of cases. It was expected that the outbreaks could then be effectively contained by smallpox eradication staff in the conventional manner. The discovery of more than 10 000 cases in India during the first search in 1973 was unexpected and, in many areas, the numbers of outbreaks proved to be far beyond the capacity of existing staff to deal with. In heavily infected areas, help was at first sought from existing health staff but this often proved counterproductive, since those who discovered cases soon found themselves burdened with the additional task of containing the outbreaks. Accordingly, arrangements were made to ensure that those who searched were not also responsible for containment.

Because of the difficulties in developing search operations and the large numbers of cases, containment in all countries until the summer of 1974 continued to consist in little more than the isolation of the patient, a rapid survey to detect additional cases, and the vaccination of household contacts and those in some 30 surrounding households. It gradually became apparent that these measures were inadequate, since outbreaks which were thought to have been contained not

only persisted but also spread to other areas. That summer, as numbers of smallpox cases decreased substantially, it became possible in India to assess carefully the failures in containment and to develop special measures to correct them. Over the succeeding months, containment measures became increasingly stringent, making it necessary to engage many additional workers, often locally recruited and trained. Other countries subsequently adopted similar measures.

Measures were taken to ensure more complete vaccination coverage in the outbreak area, the first step being to assign responsibility for each outbreak to a team leader who was a member of the smallpox eradication programme staff. He prepared a sketch map of the affected locality (Plate 10.38) and employed a team of local health workers to paint numbers on the doors of the houses or, in the case of tents, on WHO smallpox recognition cards, which were then attached to the entry flap of each tent. All residents of the village or district of a town were listed by name and by house before containment vaccination was begun, since it was found that fewer persons were then successfully hidden in an effort to avoid

vaccination. The vaccination programme, which followed the listing, required 1-3 days, the team leader and a number of vaccinators remaining in the village for 1 or more nights so as to vaccinate those who were absent during the day. Eventually, a vaccinator remained in an infected village for 28 and, later, for 42 days following the onset of the last case in order to vaccinate visitors, ensure that the patient remained isolated and detect promptly any additional patients who had been vaccinated too late in the incubation period to be protected. In Somalia, 1 or 2

vaccinators usually travelled with each affected group of nomads throughout this period.

For areas outside an infected village but within a radius of 8-10 kilometres, other teams moved from house to house to search for cases and to vaccinate. Because of the density of the population in many of the infected areas in Asia, this sometimes meant contacting 10 000 or more persons, a process that often took 1-2 weeks.

Wherever possible, patients were isolated in their houses, but even this required special measures. To ensure isolation, 4 guards were

hired who were instructed that at least one of them must remain at the door of the house, day and night, entry being permitted through a single door, the other doors being nailed shut. They made certain that the patient remained in the house, vaccinated all visitors and brought the necessary food, water and firewood to the patient. Two at a time were expected to be on duty during each 12-hour

period so that, if one had to leave, the other would remain. They stayed until the patient's last scabs had separated and were paid for their services at that time. Supervision was simplified by telling them that if, at any time, a supervisor found the house unguarded, all would be discharged without pay and new guards hired. Eventually a special book was provided in which the guards recorded the

name of each visitor, the date and the fact that he or she had been vaccinated.

In Ethiopia and Somalia, where many people lived in tents or small huts, and in congested areas of Bangladesh, it was difficult to isolate patients in this manner. In these countries, therefore, 2 other methods were sometimes used. The first was to construct for the patient a small separate hut with kitchen and latrine facilities and to surround it by a barrier of thornbush or bamboo. The second was to isolate the patient in a specially constructed camp occupied only by smallpox patients. Special guards were used in both cases. It was often difficult to gain the agreement of Ethiopian and Somali patients to be isolated, however, because, having the mild variola minor variety, they had few symptoms and could work and move about without difficulty. Compliance increased when all patients, on recovery, were given new clothes, their old clothes then being burnt.

From early 1974 onwards in India and later in Bangladesh and Somalia, larger numbers of national and international epidemiologists were recruited to head surveillance teams, with the aim of providing at least 1 such team for the supervision of surveillance and containment in an area with no more than 25 active outbreaks, an outbreak being defined as the occurrence of 1 or more cases of smallpox in a geographical location, such as a village, district of a town or nomad encampment. When a patient moved from one village to another—to be hospitalized, for example—this was counted as 2 outbreaks, since both areas had to be kept under surveillance. Once an outbreak was identified, it was considered "active" until 28 (later 42) days after the onset of the last case of smallpox. By this time, the patient's last scabs would have separated and any contacts who were incubating infection would have developed disease.

The surveillance teams were responsible for visiting each outbreak at least weekly to ensure that the prescribed measures were being taken; when the appropriate interval had elapsed after the onset of the last case, they were also responsible for organizing a search of the area lasting 1-2 days before certifying that the outbreak could be removed from the master list of active outbreaks.

Outbreak investigation required time and patience in order to identify with accuracy

the dates of onset of all cases and the probable sources of infection of each so as to reconstruct its development. For this purpose, and to promote an understanding of the concept of the chain of transmission, a special form had been employed since 1970. As the number of epidemiologists increased and the number of outbreaks decreased, more elaborate forms began to be used.

The surveillance team was responsible for investigating the source of infection or contacts of patients if they were in villages within its area of responsibility, but if the villages concerned were outside its area, the team notified its superiors so that other teams could investigate. However, the transmission of accurate information from one area to another regarding possible sources of infection and patient contacts proved unexpectedly difficult. The names of contacts as well as those of towns and villages often had to be spelled phonetically, since informants were usually illiterate. Whether this information was transmitted by telex, messenger or telephone, there were often difficulties in locating the persons or even the villages named.

The quality of supervision provided by the teams was proportional to the number of outbreaks and, as outbreaks became fewer, ever more intensive measures were applied, with the result that smallpox incidence showed an accelerating decline from June 1974 in India, and from the spring of 1975 in Bangladesh, when a similar approach was used there.

#### *Measurement of progress*

As has been noted above, it became the practice in 1973-1974 to record and monitor the number of active outbreaks rather than the numbers of reported cases. This focused the attention of programme staff specifically on surveillance-containment activities and, as a result, several standards for use in measurement were developed, designed to appraise the effectiveness of such activities.

*The interval between the onset of an outbreak and its detection* reflected the effectiveness of case detection. It was believed that it should be possible to detect at least 75% of all outbreaks within 14 days after the onset of the first case. This proved difficult. In India, a level of 57% was achieved during 1974-1975; in Bangladesh just over 70% in 1975; and in Somalia, 60% were discovered after intensive activi-

ties began in April 1977. However, by determining why in each instance the interval was longer than that prescribed, problems in detection were identified and the necessary changes in field operations could be made.

The response of containment teams was measured by the *interval between the discovery of the outbreak and the beginning of containment activities*. Ideally, containment should have begun on the day a case was reported, but this depended on the availability of manpower and transport. In most areas, there was a rapid response. In India, containment was started in 60% of newly discovered outbreaks on the day they were discovered; in less than 10% was it delayed for 3 days. In Somalia, containment was started on the day of discovery in only 40% of outbreaks when the programme began in April 1977 but in more than 90% by August.

The effectiveness of containment measures was assessed by the *interval, in days, between the beginning of containment and the occurrence of the last case*. This indicator was closely followed in all programmes from the autumn of 1974

onwards. The standard laid down was that no case of smallpox should occur in any outbreak more than 20 days after containment had started. This interval was long enough for containment vaccination to be completed and for smallpox to develop among those who had been vaccinated too late in the incubation period to be protected. From early in 1975, all outbreaks in which cases occurred more than 20 days after the start of containment activities were investigated by a senior epidemiologist to determine the reasons for failure and to advise on corrective measures.

The effectiveness of containment varied widely from area to area but improved with time. In India, additional cases occurred after 20 days in 25–30% of outbreaks in 1974, but in only 5% during 1975. In Bangladesh, a more rigorous interval of 15 days was prescribed as the standard. From November 1974, cases occurred in 25% of outbreaks after 15 days, a proportion which gradually decreased to less than 10% by June 1975. In Ethiopia, in 1973, smallpox persisted for more than 20 days in fewer than 25% of

outbreaks and the figure remained at or below this level until transmission ceased.

## CONCLUSIONS

Smallpox had many attributes which greatly facilitated its elimination; the strategic plan for eradication was a comparatively simple and inexpensive one; and, in principle, all countries supported the concept of an eradication programme coordinated by WHO. As has been pointed out in this chapter, however, implementation of the smallpox eradication programme was neither simple nor straightforward, and its successful outcome, even as late as 1976-1977, was by no means assured. The execution of this global programme, like that of any other, was inevitably complicated by a host of natural and political problems ranging from floods, drought, famine and war to such human failings as incompetence, dishonesty and personal antagonisms. These alone gave rise to formidable difficulties. No less of a problem was that of obtaining and sustaining a commitment to the programme on the part of national governments and international agencies alike, however beneficial for all peoples the global eradication of smallpox was seen to be. In consequence, serious shortages of resources and lack of cooperation continually hampered progress. Although an understandable scepticism prevailed at first as to the feasibility of eradicating this or any disease, problems persisted even when it was clear that eradication was imminent and continued throughout the process of certification.

Nevertheless, the global eradication of smallpox was ultimately achieved, a success which can be attributed essentially to four factors. The first and most important of these was the existence of an international organization through which a collective international policy could be expressed and which could call on governments and individuals in fostering and coordinating activities directed towards a common purpose. Although the execution of the programme was sometimes less than optimum, no other agency could have obtained the requisite cooperation and international commitment and participation to achieve an objective of this magnitude.

The second important factor was the dedication and competence of a substantial cadre of both national and international staff,

many in their 30s and 40s, who continually learned from experience—adapting, innovating and creating to enhance the programme's activities. They, in turn, served to stimulate and to inspire the large number of national health staff whose potential had never been fully realized.

The third factor was that the strategic plan was stated in terms of principles and illustrative methodologies rather than of directives. Moreover, the WHO Handbook explicitly encouraged programme staff to explore alternative approaches and anticipated that changes would be made as experience was acquired. As a consequence, each national programme was different and each evolved and changed over time. In addition, experiences and observations in one area were rapidly communicated to others and then appropriately adapted and applied.

Finally, the fourth factor was the recognition in 1967 that, however much was known about smallpox and however adequate the tools for eradication appeared to be, continuing research both in the field and in the laboratory would be essential. Thus, research was actively promoted throughout the course of the programme and scientists from all parts of the world responded to WHO's requests with extraordinary generosity and commitment, commonly making their observations available long before publication. Without the contributions provided by research, the achievement of smallpox eradication would have been doubtful at best.

The programme itself developed with surprising rapidity from 1967 to 1973, employing few international staff and comparatively straightforward methods of mass vaccination and surveillance—containment. In large measure, this success, where earlier efforts had failed, can be attributed to the use of quality control in the programme, something that had been uncommon in most of the endemic countries. Testing in international laboratories ensured that vaccine was potent and stable; assessment of vaccination campaigns determined whether the proportion of vaccination takes was satisfactory and the coverage adequate; and improved reporting systems provided evidence of progress towards the ultimate objective of the programme—the absence of smallpox cases.

In 1973, when endemic smallpox was confined to 5 countries in the Indian subcontinent and eastern Africa, increasing resources became available through voluntary

contributions, permitting an intensification of work in the problem areas. Surveillance-containment programmes in the 5 countries concerned became steadily more sophisticated and activities began to be documented in greater detail. Increasing numbers of international and national staff were recruited for full-time service and printed forms for recording data increased markedly both in number and in the amount of detail they contained. Without this effort, smallpox transmission would have persisted far longer than it did, if indeed eradication could have been achieved at all, given the population density and movements of peoples in the Indian subcontinent, war in Ethiopia, and the suppression of reports of smallpox in Somalia.

Until 1973, successful national programmes required only a few international advisers in addition to their own health personnel, and a handful of simple forms. Case detection and containment programmes were simple and relied heavily on existing

health service units. This is not adequately reflected in the published literature, as most papers deal with programmes during the period 1973-1977 and suggest a pattern of activity which, although necessary then, was not characteristic of programmes in the more than 20 countries which succeeded in eradicating smallpox before 1973.

Chapters 12-22, which deal with national programmes, describe more fully the wide variety of activities carried out, the problems, the successes and the mistakes. What was apparent in all, however, was the potential for extraordinary achievement on the part of WHO and national health service staffs acting in concert, given proper guidance and appropriate support in coordination, management and the allocation of resources. The potential for success in eradicating smallpox was greater in 1967 than anyone initially believed; the potential for successfully applying measures for the control or elimination of other diseases is far greater 20 years later.

## A CHRONOLOGY OF PROGRESS, 1967-1980

### Introduction

This section presents a year-by-year summary of progress in smallpox eradication (Fig. 10.4) to provide a frame of reference for the chapters describing the eradication programmes in individual countries or groups of countries (Chapters 12-23) and the certification of eradication (Chapters 24-27).

In compiling the data on the incidence of smallpox over the years, we have reviewed the available and sometimes conflicting reports and have made use of the figures that in our opinion most accurately reflect the situation at the relevant time. Some figures differ from those previously published and from those in the official national and international records. The differences are greatest for the early years of the programme, when notifications of reported cases were most delayed and incomplete. The reader who wishes to refer to the contemporaneous figures may consult the *Weekly epidemiological record*, which provided a compilation of the most recent information every 2-3 weeks and a summary of the status of the programme as a whole twice a year.

Throughout the course of the Intensified Smallpox Eradication Programme, particular importance was attached to defining which countries had endemic smallpox and which did not. Although this might seem a straightforward task, it was not so, especially during the first few years and for the smaller countries. The first summary of the situation in this period was provided in a report by the Director-General of WHO to the forty-first session of the Executive Board, which met in January 1968. In that report, 29 countries or territories were identified as being "endemic" (30 if East Pakistan, which later became Bangladesh, and West Pakistan are considered separately). Later information led to Cameroon, Southern Rhodesia and Yemen being added to the list; each had reported only a few cases in 1967 and these were at first assumed to represent importations, but they were not. However, 2 small countries—Lesotho and Swaziland—were mistakenly shown as having endemic smallpox in 1967 because of their proximity to infected areas in South Africa and their rudimentary reporting systems. Subsequent information suggests that both were smallpox-free. In later years, other countries were mistakenly identified as non-endemic because of government suppression

of smallpox notifications. This occurred for Iran from 1970 to 1972, for Iraq from 1971 to 1972 and for Somalia in 1976. Later information received from government and other sources served to clarify the situation.

### The Situation at the Start of the Intensified Programme, 1967

The first year of the Intensified Smallpox Eradication Programme saw a substantial acceleration of activities compared with previous years. This was primarily the consequence of greater financial resources and more staff becoming available from WHO and of the implementation of the regional programme in western and central Africa that received direct support from the USA. Certainly this enhanced effort started none too soon, for the number of reported cases of smallpox in the world rose in 1967 to 131 776, one of the highest totals for a decade. Little of this increase can be attributed to better reporting since few countries had yet improved their case-notification procedures. Indeed, it soon became evident that reporting was even less complete than had been feared; it had been thought that perhaps 1 case in 20 was being notified, but experience in the field began to indicate that a figure of 1 in 100 was probably nearer the mark.

The 31 countries or territories classified as having endemic smallpox (see box) were in 4 epidemiological zones sufficiently separate to make it unlikely that if one was freed from smallpox, it would become reinfected from another. These were: (1) Brazil, (2) Indonesia, (3) Africa south of the Sahara, and (4) a contiguous group of southern Asian countries extending from Afghanistan through West Pakistan, India and Nepal to East Pakistan. The eastern borders of East Pakistan and India were taken as the eastern limit of endemic smallpox on the Asian mainland, although Burma had imported cases from 1967 to 1969. The People's Republic of China was not in relations with WHO in 1967 and provided no official information, but reports by visitors suggested that smallpox was not present there; the government confirmed this in 1973.

### Programme implementation

Basic strategies and principles were issued in July in a WHO *Handbook for Smallpox Eradication in Endemic Areas*, and these were endorsed in September by the WHO Scientific

fic Group on Smallpox Eradication. Surveillance reports giving epidemiological information and documenting progress in the countries were widely distributed by WHO from September on.

WHO gave priority to the eradication programmes in the smaller of the major epidemiological zones—Brazil and Indonesia—in the expectation that success there would free resources that could be concentrated on the larger and probably more difficult zones. Brazil's programme had started in 1966, and Indonesia and WHO agreed in December 1967 on one to start in 1968. Eradication programmes began or were under way in 12 of the other 29 endemic countries at the end of 1967. Programmes in Cameroon, Dahomey, Ghana, Mali, Niger, Nigeria, Togo and Upper Volta were included in the regional western and central Africa programme supported by the USA; a programme in the Democratic Republic of the Congo started late in the year; and WHO-supported programmes were continuing in Afghanistan, Nepal and Zambia, although only the last of these represented a meaningful effort.

Many other countries decided to undertake programmes and developed plans of operations with advice from WHO; the procurement of supplies began as each plan was finalized. In India, however, a serious problem was posed by the government's decision in December 1966 to terminate its 5-year-old vaccination campaign. That country was then reporting more than one-third of the world's cases. Appealed to by WHO, it agreed that a joint India-WHO team should undertake a field assessment of the situation late in 1967 and develop an alternative plan.

#### *Other developments*

In May the first annual meeting of WHO regional and Headquarters officers responsible for smallpox eradication was held to discuss and agree upon plans, needs and priorities. In December there was held in Thailand the first of many intercountry meetings at which the staff of programmes in different countries and their WHO counterparts exchanged experiences and debated strategies.

The supply of potent, stable vaccine being crucial to success, arrangements were made for laboratories in Canada and the Netherlands to test vaccines and to help countries to develop their own production. At the same time, WHO initiated a survey of the vaccine quality and production capacity of laboratories throughout the world. More than 200 batches of vaccine were tested under WHO's auspices in 1967 (43 batches in 1966, 12 in 1965). All countries were asked to contribute vaccine and by the end of the year 15 million doses had been distributed by WHO, 4 times as many as in 1966. Over and above this, the USSR provided more than 75 million doses, mainly to Afghanistan, India and Burma, and the USA about 25 million doses for use in Africa.

After trying and rejecting several cheaper variants of the jet injector, which had come into operational use in 1967, WHO assessed the capability of the bifurcated needle—a new device by which a very small amount of vaccine could be introduced almost painlessly into the skin by multiple punctures. By the end of the year it had proved to be the instrument of choice.

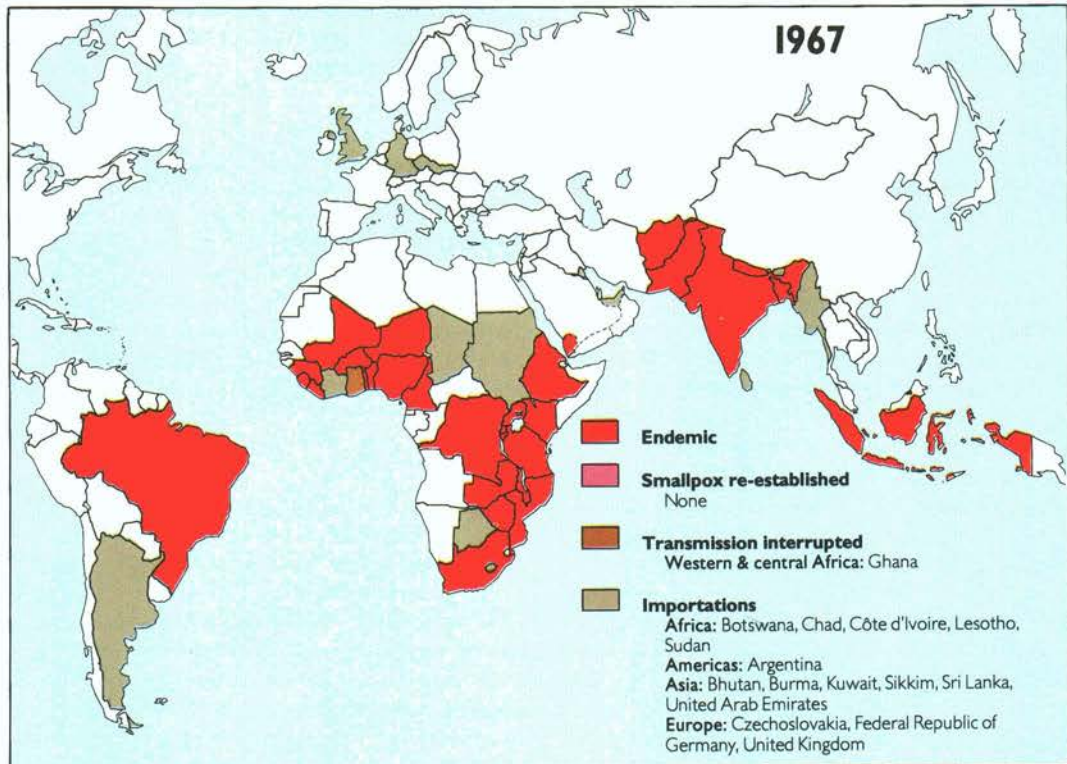

#### **Countries or Territories with Endemic Smallpox in January 1967**

*Africa, eastern and southern:* Burundi, Democratic Republic of the Congo (Zaire from 1971), Ethiopia, Kenya, Malawi, Mozambique, Rwanda, South Africa, Southern Rhodesia (Zimbabwe from 1980), Uganda, United Republic of Tanzania, Zambia.

*Africa, western and central:* Cameroon, Dahomey (Benin from 1975), Ghana, Guinea, Liberia, Mali, Niger, Nigeria, Sierra Leone, Togo, Upper Volta (Burkina Faso from 1984).

*Americas:* Brazil.

*Asia:* Afghanistan, East Pakistan (Bangladesh from 1971) India, Indonesia, Nepal, Pakistan (West Pakistan until 1971), Yemen.

**Plate 10.42.** Smallpox in the world, 1967: endemicity in 31 countries or territories.

### The Situation in 1968

During the second year of the Intensified Programme, the number of endemic countries with special eradication programmes increased from 12 to 19, and agreements were reached or appeared imminent for the commencement of programmes in 8 others. However, 4 remained as problems—Southern Rhodesia, South Africa, Mozambique and Ethiopia. The first two, with which WHO had no official contact, caused little immediate concern as they reported few cases and had a reasonably extensive health infrastructure. However, civil war in Mozambique precluded an extensive programme there, and Ethiopia declined to initiate a programme.

The number of countries with endemic smallpox in 1968 remained at 31, transmission having stopped in Ghana in 1967 but Sudan becoming infected following importations from Ethiopia. The number of reported cases diminished from 131 776 to 79 951 but this was almost entirely accounted for by a decrease in India (from 84 902 to 35 179 cases). Whether this represented better smallpox control in India or simply a longer-term cyclical trend in the incidence was unknown.

#### *Africa*

The most heartening progress was made in the regional programme in western and central Africa, which included some of the world's poorest and most heavily infected countries. By the end of 1968, 62 million persons had been vaccinated—almost 60% of the total population; in September special surveillance-containment programmes began in many of the countries. There was a sharp drop in the number of cases reported and 6 of the 10 remaining endemic countries interrupted transmission. However, civil war in Nigeria, the most populous country, threatened to extend throughout the country. In eastern and southern Africa, Uganda and Zambia also stopped transmission.

#### *South America*

Brazil, the only endemic country in the Americas, made notable progress in its vaccination campaign and, by the end of the year, was vaccinating 1.3 million persons each month. There was little improvement, however, in the notifications or the surveillance programme. Neighbouring countries in

South America also conducted vaccination campaigns but cases—all due to importations from Brazil—were detected only in French Guiana and Uruguay.

#### *Asia*

The programme in Indonesia began in 1968 and within 6 months transmission was interrupted throughout East Java, a province with more than 25 million persons. Although special vaccination campaigns were begun or intensified throughout Indonesia and other endemic Asian countries, progress was generally poor and reporting was little improved.

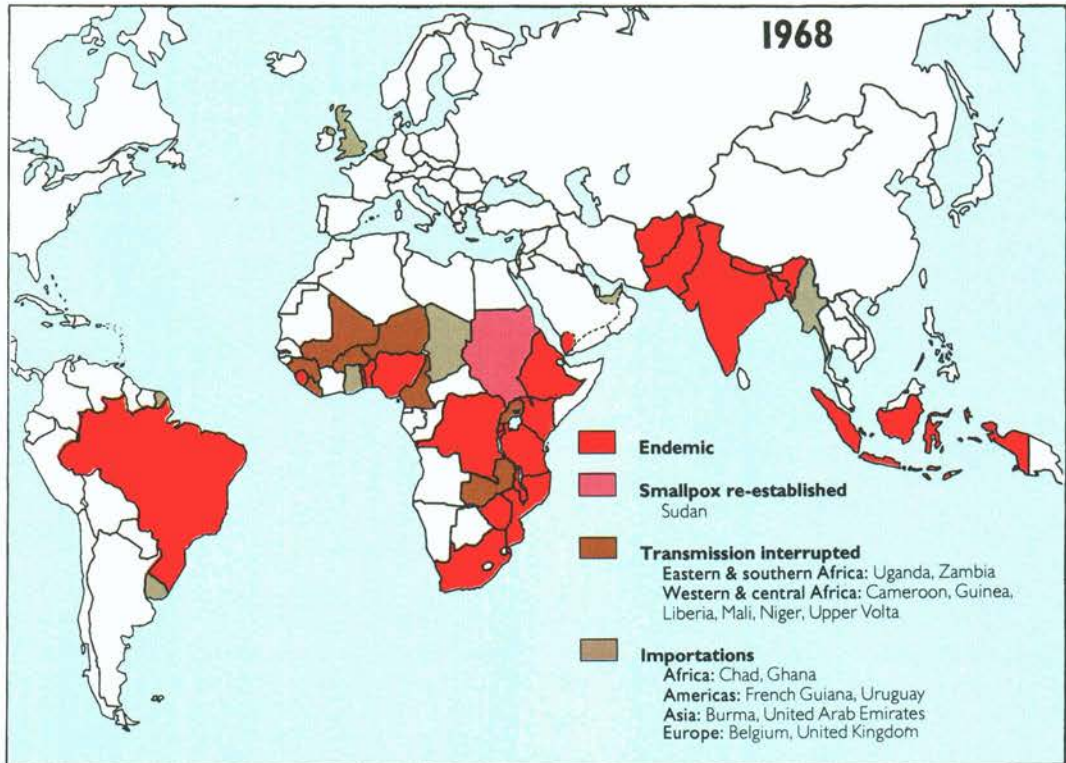

#### *Other developments*

The lack of attention to surveillance was a matter of special concern and surveillance was stressed as being "as important as the vaccination programme itself" at the Twenty-first World Health Assembly in May and emphasized again at an intercountry seminar in Kinshasa in November. Special training materials were developed to foster an understanding of the principles and methods involved.

The bifurcated needles, introduced for general use, alleviated some shortages of vaccine, but it became apparent that the endemic countries would soon need to produce much more vaccine. WHO convened experts in vaccine production to develop a manual on production methodology, and the Organization sent consultants to 24 laboratories and provided equipment and reagents to 30.

The dissemination of information about the programme and about field observations was facilitated as reports about the programme began to be published every 2-3 weeks in the *Weekly epidemiological record* from May onwards and other documents were distributed regularly to senior eradication staff throughout the world.

Activities during the first 2 years of the Intensified Programme laid a sound foundation but how this could be built upon in the field was uncertain. Although the progress in western and central Africa was encouraging, the resources made available there by the USA were greater than could then be foreseen for other countries; progress elsewhere was made primarily in the countries with the more advanced health services. At the end of 1968, the feasibility of global smallpox eradication was by no means certain.

**Plate 10.43.** Smallpox in the world, 1968.

### The Situation in 1969

Certain evidence of progress came during the third year of the Intensified Programme. Only 23 countries recorded endemic cases that year—8 fewer than in 1968—and in 5 of them transmission was interrupted. Thus, during a period of only 3 years, 15 countries successfully eliminated smallpox. Except for Yemen, they were all in Africa, and 10 of them were in western and central Africa where, at the end of 1969, smallpox persisted only in northern Nigeria. Kenya and Mozambique also ceased to report cases but because surveillance was inadequate there, the absence of cases was viewed with scepticism at first.

Although improved notification procedures led to more complete reporting in several countries, the total number of cases reported in the world declined to 54 199, the lowest figure that had ever been recorded. The optimism this gave rise to was tempered, however, by the realization that none of the countries in which transmission had been stopped was large, only Kenya having a population of as many as 10 million persons.

#### *Africa*

The successes in Africa were encouraging but 4 of the largest countries still presented serious problems. The programme in the Democratic Republic of the Congo progressed well but the country was one of the largest in Africa, transport presented formidable problems and smallpox was prevalent everywhere. In the Sudan, smallpox spread widely after being imported and civil war throughout its southern provinces made activities impossible there. In November, Ethiopia, which presented the greatest logistic challenge, reluctantly agreed to a programme but it could not begin until 1971. About South Africa, little was then known except that the number of reported smallpox cases increased from 43 in 1967 to 246 in 1969.

#### *South America*

Brazil intensified its vaccination campaign and began surveillance programmes in 4 states. Because of this, notifications improved and the number of reported cases increased from 4372 in 1968 to 7407 cases in 1969. Near the end of the year, however, the principal surveillance officers were discharged and the director of the programme resigned.

#### *Asia*

The programmes in Afghanistan, Indonesia and Nepal were substantially strengthened during 1969 but there was little progress to report in either India or Pakistan. Mass vaccination campaigns in East and West Pakistan were far behind schedule and surveillance activities were nominal, at best. India postponed the signing of an agreement to strengthen its programme and, in 1969, reported more births than primary vaccinations. India's decision that year to begin using the bifurcated needle and to terminate the use of liquid vaccine was almost the only encouraging news from a country which each year continued to report one-third to one-half or more of the world's cases of smallpox.

#### *Other developments*

Vaccine production increased in a number of the endemic countries in 1969, but shortages could be foreseen as the year progressed and more programmes began. Despite appeals for additional donations of vaccine, the quantities contributed in 1969 were smaller than in 1968.

The attainment of global eradication rested on the premise that there was no animal or other natural reservoir of the virus, but firmer evidence of this was required. In March 1969, the first of a series of biennial meetings of an informal group of research workers was convened by WHO in Moscow to plan and implement a collaborative research programme to discover whether any reservoir of variola virus existed and to elucidate the behaviour of the closely related monkeypox virus.

The promotion of surveillance-containment activities continued to meet with limited success and so the Director-General presented a special report to the WHO Executive Board which recommended for every country the "immediate investigation of every reported case of smallpox by trained investigators, the tracing of the source of infection and the prompt application of containment measures". In May, a seminar for the countries of western and central Africa provided important documentation of this approach, and another, held in Pakistan in November, for participants from 11 countries of the Eastern Mediterranean and South-East Asia Regions, stressed its importance. Translation of the methods into practice, however, continued to progress slowly.

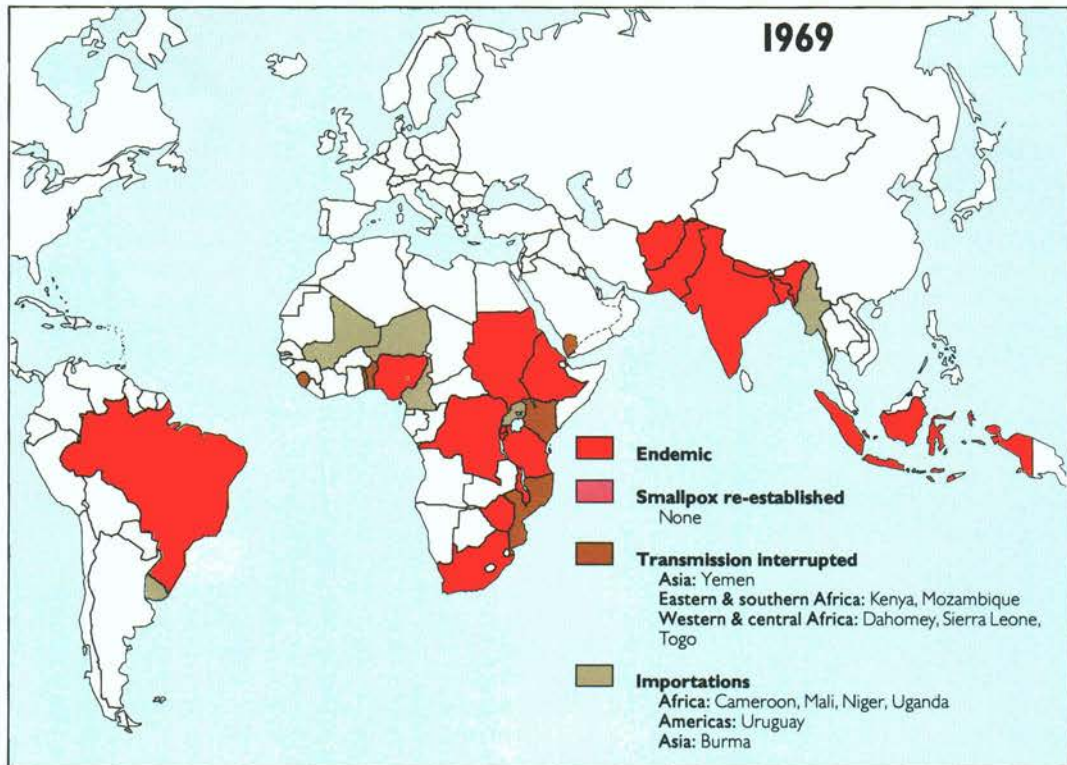

Plate 10.44. Smallpox in the world, 1969.

### The Situation in 1970

Developments in 1970 gave grounds for genuine optimism that global smallpox eradication could be achieved: only 18 countries recorded endemic cases during the year and in 6 of these transmission was interrupted—5 in Africa and 1 in Asia. Large populations were involved. With the containment of the last cases in Nigeria in May, more than 100 million persons in western and central Africa were in a smallpox-free region. Wholly unexpected was the elimination of smallpox from the densely populated area of East Pakistan (population in 1970, almost 66 million) following a brief but effective surveillance-containment programme. The reported cases of smallpox in the world during 1970 numbered only 33 693, a decrease of 38% from the record low of the previous year.

#### *Africa*

At the end of 1970, smallpox was considered to be endemic in only 5 countries in the whole of Africa: the Democratic Republic of the Congo, Ethiopia, Malawi, South Africa and the Sudan. Excellent progress was made in the Democratic Republic of the Congo during the year and South Africa embarked on a special vaccination campaign. Sudan's programme, however, progressed slowly in the accessible areas and nothing could yet be done in the strife-ridden southern provinces. Ethiopia's programme had not yet started, and the epidemiological situation in Malawi was unclear.

#### *South America*

The increased incidence of smallpox reported during 1969 had brought additional resources and support to Brazil's programme; its vaccination campaign accelerated and by the end of 1970 it appeared to be on the verge of interrupting transmission. Programmes in other countries were proceeding adequately and only 1 outbreak was detected, in an Argentinian town on the Brazilian border.

#### *Asia*

Indonesia conducted a successful surveillance-containment programme and estimated that by the end of the year 85% of its population resided in smallpox-free areas. Although transmission had been interrupted

in East Pakistan and programmes in Afghanistan and Nepal were progressing well, those in India and West Pakistan were not. In West Pakistan, a poorly conducted mass vaccination campaign lagged far behind schedule. India agreed to strengthen its national structure with WHO assistance, but otherwise remained confident as the number of reported cases continued to decrease, only 12 773 cases being reported in 1970 compared with 84 902 cases in 1967. Late in the year, however, it became evident that this was partly an artificial decrease, changes in the national notification system serving to inhibit reporting.

To encourage surveillance-containment activities in Asia, a seminar was held in New Delhi in December 1970 for countries throughout the South-East Asia Region. West African and Indonesian staff described their successes with this strategy but few changes followed.

A significant event, although it was not recognized until a year later, was the reintroduction of endemic smallpox into Iran. Major epidemics were to follow, with spread of the disease to neighbouring countries and eventually to Europe.

#### *Other developments*

With more eradication programmes in progress, increasing resources were required. Efforts to obtain additional donations met with little success, and an attempt to have WHO funds that were available in the Americas reallocated for use in Asian countries also failed. Vaccine was short throughout 1970 and donated vaccine frequently had to be dispatched on the very day it was received in Geneva. Towards the end of the year, it became apparent that it would be far more difficult to eradicate smallpox from the remaining endemic countries than it had been in those which had already been freed of the disease.

Another unexpected problem occurred when, in the second half of the year, human cases of monkeypox, clinically indistinguishable from smallpox, were discovered in Liberia, Sierra Leone and Zaire. Although monkeypox was not caused by the variola virus, the question arose whether it might behave like smallpox and be sustained by human-to-human spread. Extensive field and laboratory investigations began immediately but not until the late 1970s could the fears be fully allayed.

Plate 10.45. Smallpox in the world, 1970.

### The Situation in 1971

The fifth and sixth years of the Intensified Programme, 1971 and 1972, were years of transition between the remarkably successful period 1967-1970—when smallpox was successfully eliminated from large areas of the world with few resources—and the succeeding years, 1973-1977, when ever larger resources and more heroic measures were required to stop transmission in the few remaining endemic countries. In some parts of the world remarkable progress was made during 1971, but in others there were setbacks and portents of future problems. The year 1971 began with endemic smallpox in 12 countries, 4 of which interrupted transmission during the year, but 2 others became reinfected—Botswana and Iraq. For the first year since the programme began, the number of reported cases increased, from 33 693 in 1970 to 52 807 in 1971.

#### *Americas*

In April, the last cases in Brazil, and in the Western Hemisphere, were detected. Thus, the first of the 4 major epidemiological zones became smallpox-free. A plan of work was immediately developed for investigations and reports that would permit the certification of eradication after 2 years.

#### *Africa*

After transmission had been interrupted during the year in Malawi, South Africa and Zaire (formerly the Democratic Republic of the Congo), smallpox was endemic in only 3 African countries at the end of 1971—Ethiopia, the Sudan and Botswana (where it spread widely after having been reintroduced just as the last cases were occurring in South Africa). The programme that started in Ethiopia in 1971 found smallpox to be a far greater problem than had been expected. A staff of fewer than 80 persons detected 26 329 cases, compared with the 722 cases reported in 1970. In the Sudan, smallpox continued unabated in the southern provinces affected by civil war. It was apparent that eradication throughout Africa would need a greatly intensified effort, accompanied by a measure of good fortune, to surmount the problems of civil war.

#### *Asia*

In Asia, too, both successes and setbacks occurred. The programmes in Afghanistan, Indonesia and Nepal progressed so satisfactorily

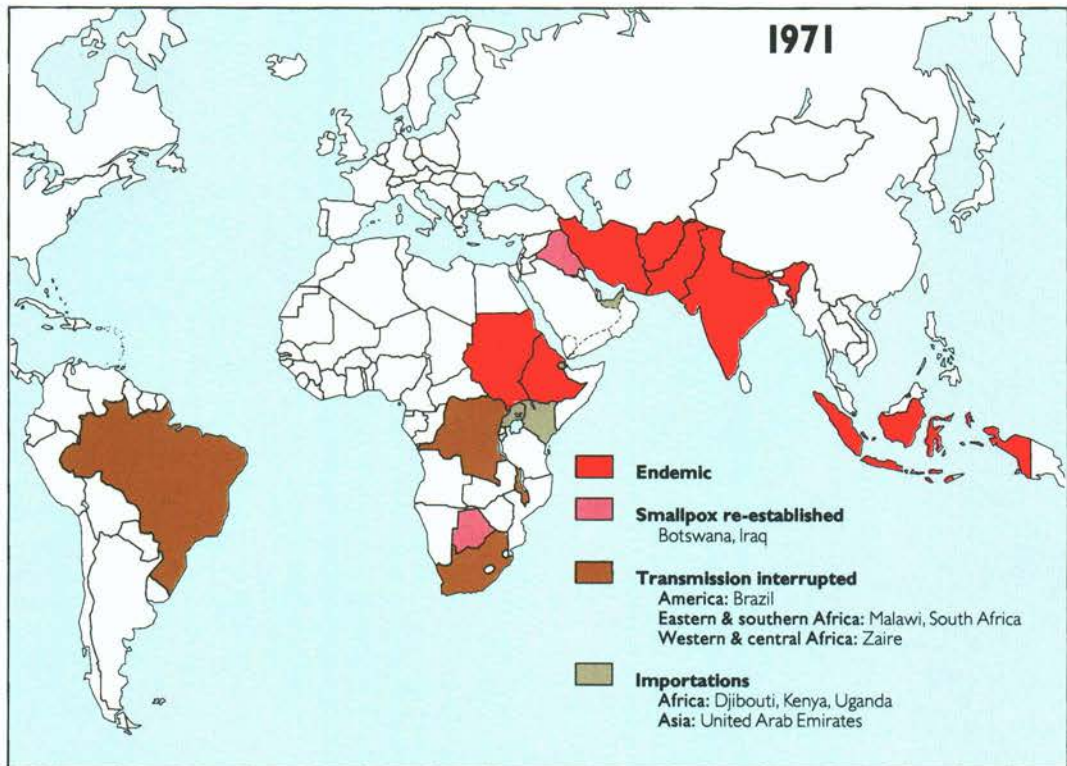

that, by the end of the year, each appeared to be on the verge of eliminating smallpox. One western state of India (Gujarat), which had been reporting 10% of the world's cases, mounted a highly effective surveillance-containment programme and succeeded in stopping transmission within a year. Epidemic smallpox, however, erupted in adjacent Indian states and, there, satisfactory programmes were slow to begin. During 1971, civil war in smallpox-free East Pakistan (which became Bangladesh in December) caused some 10 million refugees to flee to India, where most of them were housed in special camps in areas in which smallpox was prevalent. Although all persons were supposed to be vaccinated on arrival, this precaution was not taken in several camps, including one of the largest. There, smallpox broke out at the end of the year and spread throughout the camp. In West Pakistan, an unsatisfactory programme was further compromised when the country was divided into 4 largely autonomous provinces and separate programmes had to be re-established in each.

It was in the course of 1971 that the presence of smallpox in Iran first became known through numerous unofficial reports, and the government eventually acknowledged that 29 cases had occurred, all of which were said to have been importations. Much later, it was learned that smallpox had in fact been introduced from Afghanistan in October 1970 and that hundreds of cases had occurred in 1971. Subsequently, it was discovered that the disease had also spread to Iraq in November 1971.

#### *Other developments*

Sufficient progress had been made in eradication to cause the authorities in both the United Kingdom and the USA to cease their programmes of routine vaccination in 1971. However, a WHO Expert Committee on Smallpox Eradication, convened in November, presciently observed that "an effort at least equal to that made in the past 5 years" would be required to interrupt transmission in the remaining endemic areas. Although few countries were now involved, they posed difficult problems. To encourage national governments and their smallpox personnel, the WHO Headquarters staff began to spend an increasing amount of time in the field, but additional resources were not forthcoming and vaccine remained in critically short supply.

**Plate 10.46.** Smallpox in the world, 1971: eradication from Brazil.

### The Situation in 1972

Like the preceding year, 1972 was marked by notable successes and unexpected setbacks. Overall, the progress was encouraging. There were 10 endemic countries as the year began, but transmission was stopped in 5 of them in the course of the year. Successes in 3 of these—Afghanistan, Indonesia and the Sudan—represented exceptional achievements. The other 2 were Iran and Iraq, for which the true situation was not known with certainty until a year later. The number of cases of smallpox recorded in the world as a whole increased for the second successive year—65 140 cases in 1972 compared with 52 807 cases in 1971—but reporting was more complete and, by the summer, surveillance programmes of some sort were in place for the first time in all countries.

During the first quarter of the year, however, 3 serious problems emerged. In February, epidemics of smallpox began to spread across the newly independent country of Bangladesh as refugees returning from camps in India brought the infection with them. In March, Iraq and the Syrian Arab Republic officially acknowledged the presence of smallpox and soon thereafter a major outbreak occurred in Yugoslavia, imported from Iraq. Finally, in April, a WHO epidemiologist, on arrival in Botswana, confirmed that smallpox had already spread widely there.

Despite these problems, the geographical extent of the infected areas continued to diminish and it was proposed that "the final phase" should begin in September, the objective being a nil incidence by June 1974. Intercountry seminars were held in Ethiopia (September), India (November) and Pakistan (November) to launch this special effort, referred to for the first time as "Target Zero" in an issue of the WHO magazine *World health* and in the first of a series of fortnightly reports circulated by the WHO Smallpox Eradication unit.

#### *Africa*

The progress in 1972 in the 3 endemic African countries exceeded expectations. In the Sudan, the civil war in the southern provinces ceased and an effective surveillance-containment programme succeeded in interrupting transmission in December, more than a year earlier than WHO staff had expected. Botswana rapidly mobilized its resources and by the end of the year the interruption of transmission seemed immi-

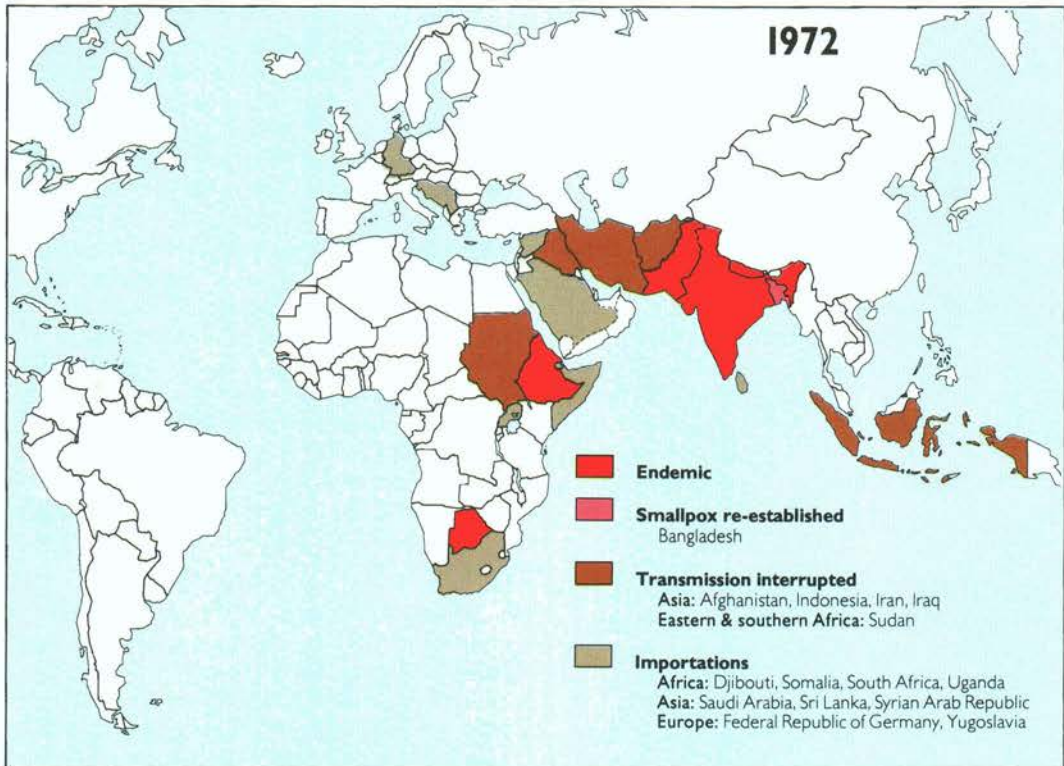

nent. As Ethiopia's programme gained momentum, the number of reported cases decreased by 35%, from 26 329 in 1971 to 16 999.

#### *Asia*

The second of the world's major epidemiological zones became free of smallpox in January, when transmission ceased in Indonesia. This was achieved in less than 4 years and with only a modest amount of international assistance. Afghanistan, where formidable geographical and cultural problems were compounded by the practice of variolation, had once been thought the country in which attempts to eradicate smallpox were the least likely to succeed. Yet it recorded its last endemic cases in October. These successes provided some much-needed encouragement to the other endemic countries of Asia, whose situation was very different. Emergency assistance had been promptly provided to Bangladesh to stem the epidemic of imported cases but, in the post-war chaos, the health services were unable to cope. More than 10 000 cases were recorded, but it is estimated from later studies that more than 100 000 cases occurred. During the autumn, major epidemics began along the densely populated Indo-Gangetic plain in southern Pakistan, India and central and western Bangladesh. Because of the very large numbers of health staff in the Asian countries and the greater interest in eradication taken by the national authorities, hope remained high that the problems might yet be surmounted, but far more serious difficulties were to develop.

#### *Other developments*

An epidemic in Yugoslavia, the first in that country for 41 years and one of the largest in Europe since the Second World War, reminded donor countries of the severity of the disease and emphasized the importance of global smallpox eradication. Increased donations of vaccine were received and the debate at the Twenty-fifth World Health Assembly was the most extensive ever, praise for the achievements being mingled with expressions of concern about setbacks in Bangladesh, Botswana and western Asia. Despite the sentiments expressed, however, voluntary financial contributions remained at much the same level as before and WHO even decreased its regular budget allocation for the programme for the following year.

**Plate 10.47.** Smallpox in the world, 1972: eradication from Indonesia.

### The Situation in 1973

The year 1973 marked the beginning of a greatly intensified effort, which steadily increased in tempo from the autumn. As the year began, only 6 endemic countries remained. Among these, Botswana recorded only 27 cases before successfully stopping transmission in November and Nepal reported 277 cases, almost all of which could be shown to have occurred following importations from India. Although the other 4 countries (Bangladesh, Ethiopia, India and Pakistan) reported large numbers of cases, large areas within each of them were free of smallpox or nearly so. It was calculated that 90% of all cases in 1973 occurred over only 10% of the land area of the 4 countries.

#### *Asia*

During the first 6 months of the year, the number of cases reported in Asia rose sharply. Although some of this increase was thought to represent more complete notification of cases, surveillance was still by no means fully satisfactory anywhere and epidemics were being discovered of a size not seen since the beginning of the Intensified Programme. By the end of June, almost 83 000 cases had been reported, including some 49 000 in India, 27 000 in Bangladesh and 6000 in Pakistan—totals which were all higher than during the comparable period in 1972.

For these countries, it appeared that a different strategy would be required to eliminate smallpox. The comparatively simple measures for case detection and containment which had previously been effective in Africa were proving inadequate in Asia. The solution proposed was to detect cases more promptly so that they could be contained before further spread occurred. In July, therefore, Indian and WHO staff decided to mobilize all health staff in India to undertake 1-week, village-by-village searches in October, November and December in the 4 states which were then reporting 93% of all cases. In other Indian states 1 or 2 searches would be conducted during this 3-month period. A similar effort was decided upon in Pakistan. The hope was to eliminate most smallpox foci during the autumn, when smallpox spread slowly, and thus to prevent widespread dissemination during the period of rapid transmission from January to April. If this was successful, it was believed that

smallpox could be eliminated during the summer of 1974. In Bangladesh, many additional surveillance teams were provided to search for smallpox in schools and markets.

The results were encouraging in Bangladesh and Pakistan, each country reporting an incidence similar to that of the year before despite much more intensive surveillance. In India, however, more than 30 000 cases were discovered between October and December, almost 5 times as many as had been found during the same period in 1972 and, indeed, more cases than had been reported in the whole country during any of the 4 preceding years. The numbers were scarcely believable but the eradication programme staff continued to be optimistic because of the commitment of government officials, the extent of activity and the interest of the health staffs.

#### *Africa*

Ethiopia remained the only endemic country in Africa and there, as in Asia, more intensive measures were taken through the addition of staff and the provision of helicopters to help cope with the rugged terrain. The number of reported cases continued to decline despite more complete notifications but logistic difficulties were increasingly exacerbated by mounting civil unrest.

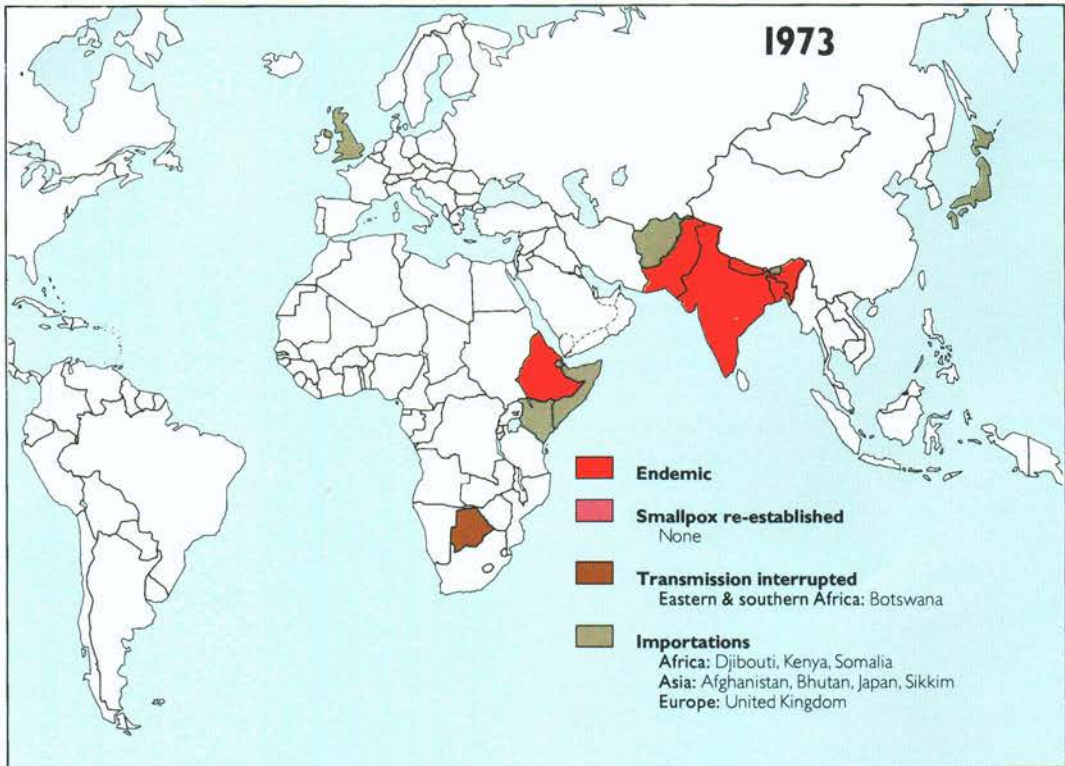

#### *Other developments*

During 1973, the first of the international commissions for the certification of eradication examined the programmes in the Americas and confirmed that smallpox had been eradicated from the Western Hemisphere.

A new concern emerged, however, about a possible natural reservoir of smallpox. This arose from the isolation—from monkey kidney tissue cell cultures in the Netherlands and from animal specimens collected near monkeypox cases in Zaire—of what were termed "whitepox" viruses, which were indistinguishable from smallpox virus. The WHO informal research group held its third biennial meeting in 1973 and developed a new agenda of work, but not for several years was this concern finally laid to rest and the "whitepox" viruses shown to be inadvertent laboratory contaminants.

During 1973, the number of recorded cases in the world—135 904—was the highest for 15 years, but the ultimate goal, "Target Zero", appeared none the less to be just over the horizon.

**Plate 10.48.** Smallpox in the world, 1973.

### The Situation in 1974

Throughout 1974, the programme as a whole steadily grew in intensity and accelerated in tempo. Successes in the 1973 autumn campaigns had encouraged the belief that a concerted effort of no more than 6-12 months would see the realization of global smallpox eradication. Additional national and international personnel as well as increased quantities of supplies and equipment supported this effort. It was concentrated on the shrinking endemic areas which in aggregate were smaller than the land area of Pakistan, one of the 5 countries concerned. With eradication apparently imminent, programme staff worked feverishly, driven partly by the fear that unanticipated natural or man-made catastrophes might thwart the achievement just short of the goal. Indeed, this concern proved well founded in 4 of the 5 countries.

#### *Asia*

In India, during the first 3 months of the year, intensified search programmes resulted in much more complete reporting but no more cases than in 1973. In May, however, explosive epidemics began, nearly 50 000 cases being detected that month and the worst affected state (Bihar) reporting more than 8000 cases in a week. Work was severely hampered by petrol shortages as well as by strikes which immobilized rail and air transport. Bihar State was further affected by devastating floods in the north, severe drought in the south, and civil disorder. These difficulties were compounded by a major epidemic in an urban industrial centre which resulted in the spread of smallpox to hundreds of distant villages in India and Nepal.

In Pakistan and Bangladesh, other problems occurred. Surveillance in Pakistan's largest province (Punjab) was suspended prematurely by over-optimistic provincial health authorities and an undetected epidemic in its capital, Lahore, quickly spread throughout the province. Bangladesh decided to restructure the health care system, resulting in the suspension of most activities, including those for smallpox, for many weeks. In the summer, monsoon rains brought the worst floods for many years to northern Bangladesh, displacing tens of thousands of persons.

During the first 6 months of 1974, more cases were recorded in Asia than had been reported annually throughout the world for

more than 15 years. By June, however, greatly expanded and better organized programmes were functioning and progress began to be measured in terms of the numbers of existing outbreaks (villages or town areas in which 1 case or more had occurred in the preceding 4 weeks). Asia had 8086 outbreaks in June.

Throughout the hot summer monsoon period, all staff were urged to maintain the pace of their work in order to take the fullest advantage of the seasonal decline in incidence. The effort proved successful. Pakistan detected its last case in November, and by the end of the year there were only 517 known outbreaks in all of Asia.

There was optimism that transmission would be interrupted by the summer of 1975. The only doubtful areas were those in which refugees were crowded in Bangladesh. The number of outbreaks in that country, which had been only 78 at the end of October, had tripled by the end of December. More than half, however, consisted of only 1 or 2 cases and hope persisted that, with the planned addition of health staff and temporary workers, the problem could be managed.

#### *Africa*

As more support became available, the programme in Ethiopia made steady progress in many areas of the country. The number of reported cases decreased from 5414 in 1973 to 4439 despite more complete notifications; in December, only 166 cases were discovered. In increasingly large areas of the country, however, field operations were severely hampered by the revolution that led to the deposition of the Emperor, by hostilities with Somalia in the Ogaden desert, and by the insurrection in Eritrea.

#### *Other developments*

The eradication of smallpox from Indonesia was certified by an international commission in April, but certification elsewhere was deferred pending further progress in Africa and Asia. Increasing efforts were made to recruit suitable international staff and consultants for the intensified campaign and to obtain sufficient contributions of vaccine and funds to permit the work to be sustained. At the end of the year WHO, for the first time, convened a meeting of potential donors to request contributions of US\$3.3 million, but only US\$2.1 million were pledged.

Plate 10.49. Smallpox in the world, 1974.

### The Situation in 1975

In 1975, the eradication of smallpox from Asia was achieved and, with it, the end of transmission of variola major virus, which caused the most severe form of smallpox. By the end of the year, endemic smallpox persisted only in Ethiopia, which had 66 known outbreaks, all of which were of variola minor, the mild form of smallpox.

#### *Asia*

In India and Nepal, the incidence of smallpox and the number of outbreaks decreased steadily. Nepal detected its last case in April and India in May. Bangladesh, however, was the site of yet another catastrophe as smallpox spread rapidly among the hundreds of thousands of persons displaced by floods and famine and from them to settled populations. Despite heroic efforts, the number of outbreaks increased from 78 in October 1974 to 1280 in mid-May 1975. India strengthened activities in border areas and quickly contained the 32 importations that occurred. Emergency funds made available by Sweden and several other countries permitted the recruitment of additional international staff for Bangladesh, and national mobilization by the Bangladeshi authorities resulted in 12 000 persons being fully engaged in eradication work. From May to August, the incidence in Bangladesh diminished rapidly but work had to be partially suspended in August, when the President of the country was assassinated. Officials feared civil war and yet another mass exodus of refugees. Fortunately, the country remained calm, smallpox eradication activities could be resumed, and on 16 October 1975 the last case occurred.

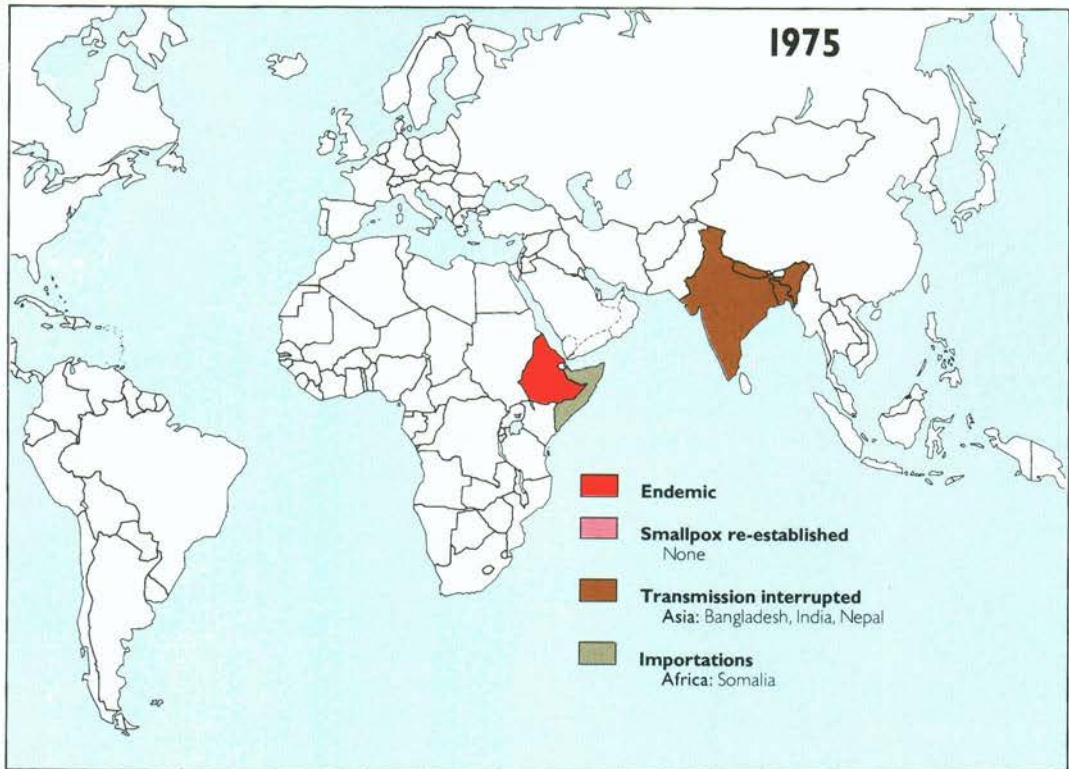

#### *Africa*

In Ethiopia, it had been expected that the eradication of smallpox would follow the same pattern as in other African countries, with transmission being interrupted 2-3 years after the programme began. By 1975, however, the Ethiopian programme had been

in operation for 4 years and although the staff were few in number, they were capable and strongly motivated. Surveillance-containment activities had been conducted since the start of the programme and more than 10 million persons had been vaccinated—nearly half of Ethiopia's estimated population. Although the population density was low and the habitations widely scattered, the mild variola minor continued to spread. The principal problem area was the rugged highland plateau, where resistance to vaccination was great and where large areas were periodically inaccessible owing to civil war. As a result of the eradication of smallpox from Asia, additional resources could be provided, permitting a 5-fold increase in staff, but the hostilities within the country hampered their efforts.

#### *Other developments*

Rumours of cases of suspected smallpox began to be received with considerable frequency from countries considered to be free of the disease. Even though they proved false, arrangements had to be made to investigate each rumour thoroughly and to publicize the findings in order to maintain confidence in eradication. Another emerging problem was that of designing and implementing an appropriate strategy to permit eradication to be certified in the African countries, some of which had detected no smallpox for many years and had consequently stopped their smallpox eradication activities. Certification of eradication in Africa had been deferred until the continent as a whole had become smallpox-free. In 1975, however, it was decided that because of the continent's vast size, the large number of countries, and the diminishing level of smallpox eradication activities, preparations for certification should commence as soon as possible. In February, the first of a number of planning meetings was held, this one being concerned with methods for certification in western and central Africa. This implied that eradication in Africa would be achieved, if not within the year, at least soon thereafter. At the end of 1975, however, that was by no means certain.

**Plate 10.50.** Smallpox in the world, 1975: eradication from continental Asia.

### The Achievement of Global Eradication, 1976-1977

As 1976 began, smallpox was known to exist in only 66 villages in Ethiopia but the interruption of transmission there and in Somalia, where it became re-established later that year, proved to be as difficult as it had been in mainland Asian countries in 1974-1975. Not until October 1977 was smallpox finally eradicated. A broad range of problems hampered the effort, from difficulties of topography and transport, civil war and eventually war between Ethiopia and Somalia, socio-cultural problems posed by nomads, variolators and large groups who resisted vaccination, to the suppression of reports of cases by the authorities in Somalia.

#### *Ethiopia*

Through mid-1976, the resources in Ethiopia were concentrated in the central and northern highland plateau areas in which civil war was raging and most outbreaks were occurring. At great personal risk to the staff concerned, these were gradually contained. Smaller numbers of staff worked in the sparsely settled south-eastern desert, where the few outbreaks occurred primarily among nomads. From past experience in similar areas of western Africa, it had been assumed, erroneously, that smallpox transmission could not long persist in such a scattered, mobile population. In the Ethiopian Ogaden desert, however, variola minor proved to be remarkably tenacious, and operations were frequently interrupted by warfare, the kidnapping of teams and the destruction of vehicles and helicopters. In August 1976, however, the last known outbreak in Ethiopia was contained and, for 7 weeks, no cases were reported from anywhere in the world.

#### *Somalia*

From 1972 until February 1976, Somalia had regularly reported importations from Ethiopia, but each was said to have been promptly detected. Late in September 1976, Somalia again reported several imported cases, this time in Mogadishu, the capital. It was learnt later, however, that these were but a few of many cases which were known to the authorities. WHO staff and consultants were quickly sent to help but they were not permitted to visit patients' houses or to travel outside the capital. Repeated mass vaccination campaigns throughout the city failed to

stop the spread of smallpox and fully 6 months elapsed before an effective national programme could be established. By then, the disease had spread widely throughout southern Somalia. A large-scale emergency effort was mounted that started in March 1977 and involved adjacent areas of Djibouti, Ethiopia and Kenya. More than 3000 cases were documented before the last case occurred on 26 October 1977.

#### *Other developments*

During 1976-1977, certification activities were organized in Asian and African countries, often requiring special studies lasting a year or more before a WHO international commission could be invited to assess the programme and to certify eradication. In April 1976 eradication was certified in 14 countries of western and central Africa, and in December in Afghanistan and Pakistan; in April 1977 in Bhutan, India and Nepal, in June in 9 countries of central Africa, and in December in Bangladesh and Burma.

It became apparent in 1977 that an independent body would be needed to advise on the measures that should be taken to give health authorities throughout the world sufficient confidence in global eradication to be willing to cease vaccination. A group of international experts, which was convened by WHO in October 1977, recommended a number of measures, including the designation by the Director-General of a Global Commission for the Certification of Smallpox Eradication. The Commission was to provide continuing guidance and oversight to the certification process and to report to the Director-General when it was satisfied that global eradication had been achieved.

The question of what should be done about the stocks of variola virus retained in laboratories around the world had long been a troublesome one. The destruction of most, if not all, such stocks was desirable but this required the full cooperation of national governments and of the laboratories concerned. As a first step, a register of the laboratories that held variola virus was prepared. Then, in 1977, the World Health Assembly requested that all variola virus stocks should be destroyed, excepting those held by WHO collaborating centres with maximum containment facilities. Many laboratories soon complied and events in 1978 served to speed the process.

**Plate 10.51.** Smallpox in the world, 1976-1977: global eradication.

### The Certification and Formal Declaration of Global Eradication, 1978-1980

The period between the containment of the last known outbreak and agreement by the Thirty-third World Health Assembly (1980) that global eradication had been achieved was as important but as difficult as had been the preceding years. The world community had to be confident of the attainment of eradication and had to know of the measures which had been taken to certify this. Laboratories had to be persuaded of the need to destroy their stocks of variola virus or to transfer them to WHO collaborating centres. Rumours of possible cases of smallpox had to be investigated and the findings publicized. Research was required to determine the nature of the viruses resembling variola virus which appeared to have been recovered from animals. An assessment of the risk of monkeypox to those living in the tropical rain forests was required as well as a determination of whether that virus could persist by human-to-human spread. Provision also had to be made for the long-term storage of vaccine reserves and for the preservation of records.

However important and substantial the activities which remained, the disappearance of smallpox quickly resulted in a diminished interest in the programme. Only with difficulty were national governments persuaded of the need to assign resources for certification activities, and WHO's budget for smallpox decreased sharply. Remarkably, however, a rigorously scheduled array of activities was completed almost as planned.

During 1978, certification activities were completed in 19 countries, including most of those in southern Africa and western Asia. This brought to 64 the total of countries where eradication had been certified by international commissions. In December, the Global Commission decided that special activities were needed in 15 additional countries. It also recommended that an official attestation be sought from all other countries to the effect that the country concerned had been free of smallpox for at least 2 years. Difficult diplomatic relationships, national sensitivities, civil disturbances and inertia caused serious problems in implementing the recommendations, but one by one the problems were overcome. On 9 December 1979, the Global Commission concluded that the global eradication of smallpox had been achieved and

approved a report that was presented to the Thirty-third World Health Assembly in May 1980.

The urgency for laboratories to destroy or transfer their stocks of variola virus became apparent when, in August 1978, 2 cases of smallpox with 1 death occurred as a result of a laboratory infection in Birmingham, England. National authorities took a greater interest in ensuring the safety of their own populations and the number of laboratories retaining stocks of variola virus decreased to 6 by May 1980, and eventually to 2.

In 1978, WHO announced a reward of US\$1000 for the report of any new case which could be confirmed as smallpox, and some 50 rumours a year were evaluated in 1978 and 1979 by field investigation and laboratory study. Most proved to be chickenpox; none was a case of smallpox.

Collaborative research on monkeypox and the "whitepox" viruses, conducted in laboratories in Japan, the United Kingdom, the USA and the USSR, revealed the troublesome "whitepox" viruses to have been laboratory contaminants. Field and laboratory studies of monkeypox virus provided increasing evidence that human infections were infrequent and that human-to-human transmission seldom occurred.

Reserves of smallpox vaccine were established and a protocol was developed for the periodic testing of samples to ensure their continuing potency.

Throughout this period, a special public information effort was undertaken to make widely known what had been accomplished and how, so that when the World Health Assembly agreed that eradication had been achieved, the general public would accept the fact more readily.

The declaration on 8 May 1980 by the Thirty-third World Health Assembly that smallpox eradication had been achieved concluded an historic chapter in medicine. Twenty-two years had elapsed since the USSR had first proposed to the Health Assembly that global smallpox eradication should be undertaken, and 14 years since the Assembly had committed special funds to a programme which it hoped would interrupt transmission within 10 years. In fact, 10 years, 9 months and 26 days elapsed from the beginning of the Intensified Smallpox Eradication Programme until the last case in Somalia.

## INTRODUCTION

The prevention and ultimately the eradication of smallpox constituted, in principle, one of the simplest and most straightforward of disease control activities. Effective long-term protection was provided by the single application of a vaccine which was easy to administer and highly stable even under tropical conditions. The presence of smallpox in an area could be readily detected because of the characteristic rash it produced, a rash which was readily identifiable by programme staff and villagers alike. Only patients with rash transmitted the infection to others, and then only to persons with whom they were in close contact. Because 10-14 days elapsed between each generation of cases, smallpox usually did not spread rapidly and epidemics took time to develop. Little more was required to control its spread than the isolation of the patient and the vaccination of his close contacts.

Despite the simplicity of both smallpox control and the strategy for its eradication, implementation of practical field programmes over a finite time span and on a global scale was a complex and difficult task. The achievement of eradication and its certification

ultimately required the cooperation of all countries. The participation of an international agency—the World Health Organization—was important, and probably essential, in ensuring such cooperation. As the international organization with technical responsibility for health programmes, WHO was requested by resolution WHA20.15 of the Twentieth World Health Assembly "to elaborate and implement the detailed plan, including the co-ordination of all international, bilateral and national efforts" for the Intensified Smallpox Eradication Programme (World Health Organization, 1973a). In carrying this out, however, WHO had no authority, other than that of moral suasion, to compel any country to initiate a programme, adhere to a plan or strategy, or contribute towards its support. For this reason, the global programme had to evolve within a framework of broad principles and expectations, pragmatically modified by reality, rather than within the confines of a comprehensive master plan having specific and enforceable time-limited goals.

In November 1967 the entire professional and secretarial staff of WHO throughout the world (including short-term consultants and

WHO agents in Zaire) numbered only 3302 persons, few indeed to cope with the array of tasks and responsibilities with which the Organization had been charged by the World Health Assembly, its governing body. Those assigned to smallpox eradication were likewise few in number, the staff of professional grade in no year comprising more than 150 persons (including consultants), of whom no more than 6 were in Headquarters and, at most, 7 in the WHO regional offices. They were expected to promote special programmes in more than 50 countries and to guide and coordinate activities which, at times, involved as many as 150 000 workers.

The programme presented unusual challenges for WHO, because the administrative structure and procedures of the Organization were primarily designed for the purpose of providing technical assistance, rather than material support, to a wide range of health projects in many different countries, few of which needed to be coordinated with others. Smallpox eradication, in contrast, required the provision of substantial material support and far closer collaboration among countries and among largely independent WHO regional offices, both in programme execution and in resource allocation.

The Director-General, Dr Marcolino Candau, had foreseen the need to mobilize substantial voluntary contributions in support of the programme but, in 1967, the Organization had had only limited experience and little success in obtaining contributions of this type. Significant donations for smallpox eradication—apart from some bilateral contributions—did not begin to be received by WHO until more than 7 years had elapsed. The consequent lack of resources constituted a serious, continuing problem and, even in the concluding years of the programme, those that were made available barely sufficed to sustain momentum. Donated vaccine, for example, was continually in short supply despite repeated appeals for assistance. The World Health Assembly was informed on a number of occasions of the need for additional funds, amounting to no more than a few million US dollars, and such funds were sought in correspondence and in meetings with potential donors, but the response was never adequate. Expenditures for smallpox eradication from WHO's own regular budget, measured in constant dollars, seldom exceeded US\$2.4 million annually, the amount initially appropriated by the Nine-

teenth World Health Assembly in 1966. Thus, restraint and compromise in field operations were necessary even when global eradication appeared imminent. Success was never a certainty even during the years immediately preceding the last known cases.

The problems of sustaining international commitment and support were formidable but no less so than those in many of the countries with endemic smallpox. Successful national programmes required a political commitment to undertake eradication, but smallpox was not a concern of high priority for some countries, even though they might have voted for World Health Assembly resolutions in favour of its eradication. Sustaining a commitment to the programme was no less difficult because, in many countries, governments changed frequently, as did the responsible health officials, and such changes led to the readjustment of national priorities. Famine, flood, epidemic cholera and the like often diverted smallpox eradication programme resources for long periods; civil war in Ethiopia, Nigeria, Pakistan and Uganda caused serious disruptions in operations; and collaboration with several governments in southern Africa, as well as some in Asia, was all but impossible owing to political constraints.

After smallpox had been eradicated, however, many persons inside and outside WHO mistakenly concluded that the achievement could be attributed to a generously financed, enthusiastically supported and authoritatively directed programme similar to a military campaign. That the programme had none of these characteristics is apparent from this and the succeeding chapters.

This chapter describes the context within which the programme functioned in WHO and how the overall campaign developed and matured, how national programmes were established, how international coordination was achieved, how personnel were recruited and budgetary problems resolved, how supplies of vaccine were obtained and handled, and how research contributed to the effort. All these activities were interrelated, and critical constraints or important developments in one area affected progress in others. For clarity of presentation, different elements of the Intensified Programme are discussed individually, beginning with the overall strategic plan and the programme's administrative structure, relationships and personnel at the international level. This is followed by a

description of the way in which national governments became committed to the programme. A discussion of resources, surveillance and research, from an international perspective, is followed by a general description of the approaches adopted and results obtained in national programmes of vaccination and surveillance. To provide an overall perspective and an introduction to the chapters describing national programmes (Chapters 12-23) and certification activities (Chapters 24-27), a brief chronological summary of events concludes the chapter.

### THE STRATEGIC PLAN

As described in the Director-General's report on smallpox eradication to the Nineteenth World Health Assembly (World Health Organization, 1966b), the strategic plan for eradication during the Intensified Programme was 2-pronged: (1) mass vaccination campaigns in which freeze-dried vaccine of assured quality was employed and which were assessed by special teams, and (2) the development of a surveillance system for the detection and investigation of cases and the containment of outbreaks. In the execution of the programme, 3 principles were considered to be of special importance: (1) all countries would need to participate and their efforts would require regional and global coordination; (2) flexibility and adaptability would be required in the implementation of national programmes; and (3) ongoing research, both in the field and in the laboratory, would be needed to evaluate progress, define alternative directions and methods, and solve problems as they arose.

To foster a common understanding of principles and procedures among a geographically far-flung programme staff, a comprehensive mimeographed manual entitled *Handbook for Smallpox Eradication Programmes in Endemic Areas*, hereafter referred to as the WHO Handbook, was issued by the Organization in July 1967 (SE/67.5 Rev. 1, World Health Organization). It was an elaboration and adaptation of a manual developed in 1966 for the programme supported by the USA in western and central Africa (see Chapter 17). The foreword to the WHO Handbook encouraged programme staff to innovate and to adapt as needed, since programmes should

evolve and change with experience. For this reason, the WHO Handbook was deliberately referred to as a "draft", in the expectation that revised versions would be prepared in subsequent years on the basis of field experience. Because of the small number of staff available in Geneva and the speed with which the programme developed, no revised version was ever issued, other means being used for passing on from one country to another new and important observations and approaches. The WHO Handbook included a wide variety of information, ranging from an account of the clinical features of smallpox and the methods used in laboratory diagnosis to a description of operational approaches for vaccination campaigns and surveillance programmes; it also described methods for use in health education, and the management of administrative and transport services. The Handbook concluded with a section describing more than 20 subjects of interest for field and laboratory research.

The basic strategy, with certain modifications in emphasis and subsequent elaboration of methods for its implementation, withstood the test of field experience. Vaccination campaigns, however conducted, were expected to reach at least 80% of the population in all areas, and higher, but unspecified, rates of coverage in the more densely populated cities and towns. The figure of 80% was not based on any epidemiological criterion, but represented what was believed to be an achievable goal in a well-conducted programme. As an indicator of the use of potent vaccine, the plan called for a take rate of at least 95% for primary vaccinations. To determine whether these objectives were being met in a given area, independent assessment teams were expected to monitor the results in a sample of the population soon after the campaign had concluded in that area.

Although assessments of coverage and take rates were considered to be important quality control measures in the vaccination campaigns, the WHO Handbook emphasized that "the success of the programme, therefore, is appraised ultimately by the occurrence or absence of endemic smallpox and the *principal assessment technique, accordingly, is surveillance*". Surveillance was to be based on a reporting system in which all existing medical and health units participated. This was to be supplemented by the immediate investigation of reported cases and a critical review of outbreaks to determine how and why small-

pox was being spread. The WHO Handbook stated that:

"... surveillance thus is an essential component of the programme since the term 'eradication' implies that the number of indigenous cases of smallpox is '0'. However extensive a country's vaccination campaign, however accurately assessed, a country with an inadequate system for surveillance cannot determine whether ... eradication has been achieved."

Since it was recognized that surveillance was a new concept and might be difficult to implement in highly endemic countries, a phased programme for its development was proposed (see Chapter 17, Table 17.4).

Mass vaccination was a familiar and readily acceptable concept to public health officials. Assessment of the quality of work and of progress, on the other hand, had not been common practice. Few were accustomed to measuring the success of their efforts and many, in fact, had never questioned whether the vaccine in use was satisfactory or had been properly stored. Both assessment and surveillance proved difficult to incorporate into most programmes.

### THE WORLD HEALTH ORGANIZATION

Among the international agencies, WHO has played a pre-eminent role and acquired substantial experience in providing technical assistance and cooperation for health programmes and in the development of international health policies. Other international agencies—e.g., UNICEF and the United Nations Development Programme—have provided substantial material assistance for health programmes, but WHO, from the time of its foundation, has seen its main task as that of providing technical guidance (Finkle & Crane, 1976). WHO, like all large administrations, has gradually evolved its own patterns and traditions of management and, while a full exposition of this subject is beyond the scope of this book, certain features are important to an understanding of the course of development of the global smallpox eradication programme.

In a comparative analysis of 8 major international organizations, Jacobson (1973) characterized the role of the Director-General of WHO as being unusually significant and influential. He described the Organi-

zation as a "strong and stable system", but noted that it was "dominated by the ideology of medicine" and "by a strong commitment to regionally decentralized service activities". Because of this decentralization of activities and responsibility within WHO, its regional directors have also played unusually important roles. They and the Director-General are the only elected officials of the Organization. If after a term of office of 4-5 years they wish to be reappointed, they must stand for re-election by Member States. The factor of re-election inevitably has a bearing on their decisions regarding the recommendation of projects, budgetary allocations to countries, appointment of staff by nationality, and other matters. Continuity of the elected leadership, however, has been the norm. Although the first Director-General, Dr Brock Chisholm, served for only 5 years (1948-1953), his successor, Dr Marcolino Candau, served for 20 years (1953-1973), and Dr Halfdan Mahler has held the office since that time. For most regional directors, a long term of office has likewise been the norm.

### The Members and Governing Bodies of WHO

The World Health Assembly, which decides WHO's policies and programmes, consists of delegates representing Member States, each Member State having one vote. It normally meets once a year, usually in May. Guidance to the Health Assembly is provided by the Executive Board, a smaller body, whose members serve in a personal rather than an official capacity but are designated by the governments of Member States elected by the Health Assembly. The Board meets twice a year, the main meeting being held in January, while a second, shorter, meeting takes place immediately after the Health Assembly.

The Twelfth World Health Assembly (1959) and the Nineteenth World Health Assembly (1966) committed WHO to the global eradication of smallpox although some countries were not then Members of the Organization and hence not party to these decisions. Among those which, in 1966, were not yet Members or were not yet directly represented were the People's Republic of China, the German Democratic Republic, the Democratic People's Republic of Korea and the Socialist Republic of Viet Nam. Until the 1970s, no official communication between

Fig. 10.1. WHO regional offices and the areas they served, December 1967. Whereas there were 167 Member States and Associate Members of WHO in December 1986, there were only 129 when this map was prepared (from World Health Organization, 1968a). A number of countries or territories shown here as served by WHO regional offices were not directly represented in WHO in 1967, the largest among them being the People's Republic of China

WHO and these governments was possible and little official information was available from some of them about the status of smallpox in their countries. None was thought to have endemic smallpox in 1966, although it was not possible to confirm this until after they became Member States of the Organization. Besides these countries, there were 4 other large territories, all in Africa, which in 1966 either no longer participated in WHO (South Africa) or were represented by colonial powers (Angola, Mozambique, and Southern Rhodesia). All except Angola had endemic smallpox in 1967. Until the 1970s, however, it was difficult or impossible for WHO to communicate with these countries as well, either about the occurrence of smallpox or about the status of their programmes. Thus, effective universal participation in the smallpox eradication programme was not achieved until a number of years after the Intensified Programme had begun, and not until 1979 were communications adequate with all countries so that global eradication could be certified.

Each Member State is attached to one of WHO's 6 regions (Fig. 10.1), only 4 of which had endemic smallpox in 1967—Africa, the Americas, South-East Asia and the Eastern Mediterranean. Regional committees, at which Member States of the respective regions are represented, meet once a year to decide regional policy and to examine the regional director's proposed programme budget for transmission to the Director-General and inclusion in the Organization's global programme budget.

The type of representatives sent by Member States to the Health Assembly and the regional committees had a bearing on the smallpox eradication programme and on the outcome of resolutions. An analysis of delegates to the Twentieth World Health Assembly (1967) showed that 80% were representatives of health ministries (Jacobson, 1973); while that was logical and often advantageous, it was sometimes a handicap to obtaining voluntary contributions from governments and to securing national commitment to undertake eradication programmes. Volun-

tary contributions from the industrialized countries were usually provided by a development agency separate from the ministry of health and, as experience showed, liaison between the two was frequently deficient. Programme policies and needs identified by the World Health Assembly were often not understood by the development agencies and sometimes, because of this, appeals for voluntary contributions went unheeded. The way that the countries with endemic smallpox were represented also gave rise to problems. Ministries of health, to which most delegates belonged, were often politically weak, the minister often not being of cabinet rank. Decisions with regard to the allocation of national resources were often made elsewhere in government—e.g., in planning departments, few of whose members attended the World Health Assembly. Thus, the commitment of some Health Assembly delegates to undertake national programmes meant little from the point of view of their implementation.

### Role of the Director-General

Decisions on policy and budgetary allocations were ultimately the responsibility of the Health Assembly, acting on the advice of the Executive Board but, as Jacobson (1973) points out:

"The Director-General initiates the process of formulating WHO's budget and establishes guidelines ... Later he compiles the proposals of the headquarters staff and the regional offices. At both stages he has opportunities to make important judgments about allocations among functions and regions. The formal position of the Director-General makes him an initiator, controller and vetoer as far as programmatic decisions are concerned."

The minutely detailed budgets proposed by the Director-General were seldom altered either by the Board or by the Health Assembly; moreover, after they had been approved, he had considerable discretionary authority to transfer funds from one programme to another and from country to country as need and opportunity dictated.

Changes in WHO policies were less likely to be impeded by long-established career staff than in many other large administrations. Relatively few had career service appointments in comparison with some other international organizations. From the time of

WHO's foundation, a continuing turnover of personnel had been considered helpful in sustaining a high level of professional expertise. Thus, in 1969, only 20% of professional staff at Headquarters and the regional offices and about 5% of those working in field projects had career service appointments (Jacobson, 1973). In the same year, only 29% of the staff had served in WHO for more than 5 years.

For these reasons, WHO's limited financial support for smallpox eradication prior to 1967 (see Chapter 9) reflected the concerns and priorities of the Director-General at least as much as those of the Health Assembly. His attitude in turn reflected, in large measure, his scepticism as to the possibility of achieving global smallpox eradication until basic health services in all countries had been greatly strengthened, a scepticism shared by many scientists and health officials at that time. His doubts had been reinforced by the recommendation of the WHO Expert Committee on Smallpox (1964), discussed in the preceding chapter, which implied that everyone would have to be vaccinated to ensure eradication. Since, for example, there were tribes in the Amazon basin with which national authorities had little or no contact, it was apparent that universal vaccination was not then possible. For the Organization to be committed to an unattainable objective when, at the same time, its only other global eradication programme—that for malaria—was in serious difficulty, could jeopardize WHO's technical credibility. Moreover, the Director-General foresaw the possibility of another single-purpose eradication programme diverting national and international resources and attention from the important, but difficult and less glamorous, task of developing basic health services. He frequently pointed out that, if additional funds were to be allocated to smallpox control, they should be provided in the form of voluntary contributions by the industrialized countries, which would benefit by having fewer imported cases of the disease to deal with.

The decision, in 1966, by the Nineteenth World Health Assembly to establish a special allocation for smallpox eradication in the Organization's regular budget required WHO to undertake a more vigorous programme, but the additional funds did not allay the Director-General's concerns about the Intensified Programme's prospects of success.

**Plate 10.1.** Halfdan T. Mahler (b. 1923) took office as Director-General of WHO in July 1973. His long career in international public health had included almost 10 years as a senior WHO officer with the Indian national tuberculosis programme. This involved the application of methods of operations research that proved valuable when, as Chief of the WHO Tuberculosis unit, 1962-1969, he worked with the Smallpox Eradication unit to overcome the problems of the simultaneous administration of BCG and smallpox vaccines. He had been an Assistant Director-General of WHO from 1970.

### WHO Programme Management in Geneva

The management and supervision of technical programmes at WHO Headquarters differed from what an organizational chart (Fig. 10.2) might suggest, as is indeed the case with many organizations. During Dr Candau's term of office as Director-General, technical programmes at WHO Headquarters were usually monitored by the Director-General and the Deputy Director-General, Dr Pierre Dorolle, through direct contact with the chiefs of the respective technical units. The senior intermediate positions in this inter-governmental organization—assistant directors-general and directors of divisions—had many representational duties and were often relatively little concerned with the day-to-day activities of the technical units. Over the 20-year period during which Dr Candau was Director-General, the Organization grew in size and the number of activities and technical units multiplied,

making direct supervision of each of them increasingly difficult. Smallpox eradication programme staff seldom met the Director-General until Dr Halfdan Mahler assumed the post in 1973. Contacts with the responsible assistant director-general were likewise uncommon before Ladnyi's appointment to this position in 1976. Among those who served as directors of the Division of Communicable Diseases, Dr Karel Raška, who held this post until early 1970, took a particular interest in smallpox eradication and actively supported the programme.

The Smallpox Eradication unit had, of necessity, a closer, continuing relationship with those responsible for WHO's administration and finance. Until 1971, the Assistant Director-General responsible for this area, Mr Milton P. Siegel, an active proponent of smallpox eradication, directed these activities and those reporting to him took a similar interest in the programme. Both during and after his period of tenure, most of them went out of their way to provide help and guidance.

Throughout much of the smallpox eradication programme, the unit, as far as the management of its technical activities was concerned, functioned relatively autonomously. This meant that it could alter smallpox programme policies and make other decisions quickly, but it made it more

Carney (b. 1920), Chief, Finance and Accounts, 1972-1980.

difficult to implement the necessary changes and to persuade regional directors, government officials and donor agencies of the programme's need for support.

### The Smallpox Eradication Unit in Geneva

The Smallpox Eradication unit in Geneva consisted throughout most of the programme of only 10 persons—4 medical officers, 1 administrative officer, 1 technical officer and 4 secretaries. Even this number had originally been considered excessive by senior WHO staff, who then envisaged the unit's activities as consisting of little more than ensuring that each country received adequate resources for conducting mass vaccination campaigns (see Chapter 9). During the first year of the Intensified Programme, however, it became apparent that far more than this was required and, indeed, that additional personnel would be useful. However, requests for additional staff were rejected, in part because of pressures by WHO Member States to limit the size of Headquarters staff. But short-term consultants could be recruited, and in 1968-1969, Dr Gordon Meiklejohn served on the staff during a sabbatical year's leave from the University of Colorado; in 1969-1970, Dr

Paul Wehrle, on similar leave from the University of Southern California, also worked in the unit. Every year subsequently, each undertook special tasks on behalf of WHO for 4-6 weeks during his university vacation.

Some compensation for the dearth of staff was provided by the fact that many of those in the Headquarters Smallpox Eradication unit served for long periods; this ensured continuity and consequently a greater ability to anticipate the problems of the Organization and of governments in the endemic countries (see Table 10.1).

Late in 1970, an interregional team of 3 additional medical officers was authorized to provide short-term emergency assistance wherever required and to help in establishing surveillance programmes where these were lacking. One was recruited and assigned to Ethiopia, in which that greatly understaffed programme was just beginning, and 2 to West Pakistan when that region was divided into 4 provinces with 4 essentially autonomous smallpox programmes (see Chapter 14). As their presence in these assignments continued to be necessary, they were effectively lost to the Headquarters complement, though remaining chargeable to the Headquarters budget since the Regional Office for the

Eastern Mediterranean stated that it had no funds with which to take them over. Other efforts to increase the size of the Headquarters Smallpox Eradication unit were unsuccessful. In consequence, the few professional staff based in Geneva of necessity undertook a wide range of activities both at Headquarters and in the field. As the programme progressed, they had to travel more and more, to the point that most were in travel status for 50–70% of the time.

A partial listing of the activities undertaken by the unit gives some insight into the nature of day-to-day operations. In the interests of the morale of field staff and the acceleration of operations, priority was given to all communications from the field, the aim being to respond to queries or requests within 48 hours of receipt. A surveillance report was prepared for publication every 2–3 weeks in the *Weekly epidemiological record* and more extensive summary reports on the programme twice a year. Voluntary contributions were repeatedly sought through special mailings and visits to governments and other potential donors. Arrangements were made for the testing of vaccine and for its shipment to a central depot in Geneva. Stocks of

vaccine, bifurcated needles, jet injectors, kits for the collection and dispatch of specimens and training aids were kept in Geneva and sent on request, to countries. Specimens from patients were received weekly from different countries, repacked and sent to reference laboratories for testing; the results were sent by telex to those submitting the specimens (see box). Each year 1–2 international meetings were arranged for senior smallpox eradication programme staff from regional groups of endemic countries, as well as annual conferences of WHO's regional smallpox advisers, biennial meetings of the research group concerned with monkeypox and related problems, meetings of the WHO Expert Committee and the WHO Scientific Group on Smallpox Eradication, and a special meeting dealing with vaccine production. Various training and educational instruments were prepared—manuals, posters, slide series, teaching exercises and films. An extensive correspondence was conducted on the recruitment of personnel, regional and national budgets and programmes, and the procurement of supplies and equipment. Press releases were prepared and media queries answered. Reports from field staff dealing with their work and observations were edited and published twice a month.

Because of the heavy travel commitments of the unit's staff, there was insufficient time to perform all these functions well. Had there been adequate manpower, the following 3 activities, in particular, could usefully have received more attention and this, almost certainly, would have reduced the time required to achieve eradication: (1) field studies to define more precisely the status and epidemiology of smallpox in different areas and to evaluate alternative methods of smallpox control; (2) field demonstrations, extending over 2–3 months, of surveillance-containment methods; and (3) personal contacts with potential donors to explain the programme and to seek support.

The Smallpox Eradication unit had comparatively few collaborative relationships with other technical units at WHO. One other unit with which it worked closely was that responsible for implementing the provisions of the International Health Regulations. This unit received weekly telegraphic reports of cases of the quarantinable diseases, including smallpox, and published them in the *Weekly epidemiological record*. These activities are described below, in the section

**Plate 10.4.** Participants in the meeting of the WHO Expert Committee on Smallpox Eradication in November 1971. The chairman (right) was Francis C. Grant (b. 1924) of the Ministry of Health of Ghana, who had been a smallpox eradication consultant for WHO in Burma in 1970. The rapporteur was Paul F. Wehrle (b. 1921), a United States professor of paediatrics who had helped to establish the global eradication programme while serving as a WHO consultant in Geneva, 1969–1970.

**Plate 10.5.** Staff of the Smallpox Eradication unit at WHO Headquarters. **A:** Donald Ainslie Henderson (b. 1928), Chief, 1966–1977. **B:** Isao Arita (b. 1926), Medical Officer, 1965–1976; then Chief, 1977–1985. **C:** John S. Copland (b. 1930), Administrative Officer, 1967–1977. **D:** John F. Wickett (b. 1944), Technical Officer, then Administrative Officer, 1970–1980, and consultant, 1983–1987. **E:** Susan E. Woolnough (b. 1948), secretary to Henderson and Arita, 1970–1985. **F:** Celia I. Sands (b. 1945), secretary, 1969–1981.

entitled "Surveillance and notification of smallpox cases". Collaboration with such units as those dealing with health education and maternal and child health would have been logical and potentially productive but most of them were small, with only 2 or 3 professional staff, few of whom were directly concerned with field operations. The only programme of substantial size and with extensive field activities was that for malaria eradication, but by the mid-1960s it had begun to encounter major problems which fully occupied its staff. The only other immunization programme, until 1975, was that for tuberculosis, which was the responsibility of the Tuberculosis unit. However, the staff of that unit were also few in number and much of their time was devoted to field trials aimed at assessing the efficacy of BCG vaccination.

### WHO Regional Offices

The WHO regional offices were positioned administratively between WHO Headquarters and countries and were expected to play a major role in the development and coordination of all types of country programmes in their respective regions. For them, the Intensified Smallpox Eradication Programme differed from others for which they were responsible in that it required more or

less simultaneous activities in all countries, both to monitor the occurrence of smallpox and to undertake programmes to eradicate the disease or to detect and contain importations. Its needs were different, therefore, from those of tuberculosis control or maternal and child health, for example. Programmes such as these were often country-specific, and it was usually of little moment to the region as a whole or to other countries whether one or more countries did or did not undertake special activities or whether a given disease was widely prevalent elsewhere or not. It might seem that experience acquired in malaria eradication would provide a model, but it did not. National malaria eradication programmes had been implemented with WHO assistance in South America and Asia but in only one country of sub-Saharan Africa (Ethiopia). Most of the smallpox-affected countries that also had endemic malaria had not progressed beyond the "attack phase", in which systematic spraying was the primary activity. Even where there was surveillance it tended to be purely national in character, since knowledge of the malaria status of neighbouring countries was of little interest except in certain border areas.

Most WHO regional offices did not, at that time, initiate health programmes. Rather, they responded to requests for assistance from governments. Owing to budgetary constraints, the travel of regional office staff

### Processing of Specimens from Suspected Smallpox Patients

Specimens from suspected smallpox patients from all parts of the world were sent to Geneva and, once a week, sent by air, alternately to the WHO collaborating centres in Atlanta (Center for Disease Control) and Moscow (Moscow Research Institute for Viral Preparations). This practice was followed so as not to overburden either laboratory. Most specimens were received in Geneva in collection kits designed and provided by WHO (see Plate 10.6). The kit included a stylette and swabs for taking specimens, and a screw-capped glass vial into which the specimen was to be placed and which, in turn, fitted into a screw-capped metal container. Two copies of a form providing identifying information about the patient were wrapped around this second container and the contents placed in yet a third screw-capped cardboard shipping container. When received in Geneva, only the outer container was opened, one copy of the form removed and the specimen logged in. Laboratory results were sent to Geneva from the laboratory by telex or telephone and relayed, in turn, to the responsible health administration.

Although no problems arose with this method of handling specimens in Geneva, it is seen, in retrospect, to have been less than satisfactory, since it assumed that neither the form nor the second container was contaminated with variola virus and thus capable of causing infection. However, health officials in some countries sent specimens in other types of containers, including envelopes and small boxes, which were sometimes only partially sealed. Miss Sands, who dealt with the specimens, was revaccinated every year, as were all the staff, but she opened and processed the specimens at an ordinary secretary's desk in an open room.

While unthinkable now, the system, at the time, appeared to provide reasonable safeguards against the chance infection of others in Geneva. The infection of personnel handling specimens, even in laboratories, was uncommon and, until the mid-1970s, laboratory precautions consisted in little more than the vaccination of personnel. The occurrence of smallpox in 1978 in Birmingham, England, in a person exposed to virus carried by an air duct from one room in a laboratory to another demonstrated the need for more stringent precautions.

Another concern present throughout the course of the programme was that of the possible loss of specimens in shipment. Thanks to a rigorous, continuing check of bills of lading against receipt of shipments, this did not occur, but, as a precaution, specimens sent from Geneva to Moscow and Atlanta were packed in large containers which would be less likely to be mislaid.

tended to be restricted. Efforts to persuade WHO regional directors that the needs of global smallpox eradication called for a somewhat different approach met with only limited success, varying from region to region. The Region of the Americas and the Eastern Mediterranean Region immediately appointed full-time advisers on smallpox eradication, and a year afterwards two medical officers in the South-East Asia Region were given full-time responsibility for smallpox eradication. In these regions, programme planning, the recruitment of staff and the procurement of supplies and equipment were most efficiently conducted. In the African Region, however, until certification activities began, responsibilities for the smallpox eradication programme were assigned as

a part-time responsibility to the adviser on tuberculosis or on all communicable diseases. Not only did this region include more countries than any other, with some of the world's least developed health systems but, in addition, communications between the regional office and countries were poor and travel was difficult. As is described in the chapters dealing with field operations, there were continuing problems of every type in endeavouring to develop and support national programmes. In all regions, however, a lack of personnel in the regional offices and the customary constraints on their travel handicapped programme development. Where only a single adviser was involved, his absence on leave or duty travel meant that communications often went unheeded and

other activities, such as recruitment and the procurement of supplies and equipment, slowed down or ceased altogether. As a result, Headquarters staff travelled far more frequently and extensively than might otherwise have been necessary for a programme having a regional structure.

The regional offices were at that time likewise largely unaccustomed to the coordination of plans, needs and resources within a global context. To try to achieve better coordination, the Headquarters Smallpox Eradication unit held annual meetings for those responsible for smallpox eradication in each region to discuss goals, plans and progress. At the meetings, priorities were decided and needs identified, including funds, vaccine, vaccination instruments, personnel, and training aids. Such meetings were usually held in conjunction with a WHO-organized multinational meeting of programme staff, at which strategy and recent field observations were also discussed. Whatever the venue, it was always necessary to make a special appeal to one or several of the regional directors to obtain permission for advisers to attend, a permission which was

usually but not always granted and then only on the condition that Headquarters funds would be used for travel. Although the meetings proved invaluable, it was never possible to achieve a rational allocation of funds, as will be discussed later.

### WHO Representatives in Countries

The WHO representatives in countries provided the point of contact between WHO and the countries; they were assigned to most developing countries to assist in formulating policy and developing projects, and to provide administrative and technical guidance to WHO-supported programmes. Some of them had had many years of experience in international health work, but most were recent recruits who had held senior positions in their own national health services. They took up their positions after a short briefing, largely of an administrative character, and usually met their regional directors and other WHO representatives once or twice a year. Few were experienced or knowledgeable in smallpox eradication and, because of their

**Plate 10.7.** **A:** Nicole Christiane Grasset (b. 1927) served as adviser for smallpox eradication in the South-East Asia Region of WHO, 1970–1976, succeeding Jacobus Keja who had been an adviser there from 1967. **B:** Ahmad J. Hajian (b. 1920) was the smallpox eradication adviser in the Eastern Mediterranean Region of WHO, 1971–1977, replacing Ehsan Shafa (Plate 10.12).

numerous other responsibilities, few could make any substantial contribution specifically to the Intensified Programme.

### Smallpox Eradication Programme Staff

The quality and commitment of international staff proved to be one of the most important factors in the successful eradication of smallpox, and considerable time and effort were expended by the Smallpox Eradication unit on recruiting them. The task was not an easy one, however. Epidemiologists with experience in infectious disease control were particularly desirable because of the need to initiate and foster epidemiological surveillance. In 1967, however, few were available, and of those who were, almost none had ever seen cases of smallpox. Most were recruited on the strength of their experience in the management of health programmes, special consideration being given to basic competence and motivation. Specialized training in smallpox eradication methods would have equipped them better for their assignments but many difficulties were encountered in providing it. Thus, adequate numbers of fully qualified staff did not become available until the Intensified Programme was well advanced.

The provision of special training programmes in smallpox eradication proved impracticable, except for international and senior national staff working in the programme conducted with United States assistance in western and central Africa. For these, from 1966 onwards, the Communicable Disease Center (which has been renamed on several occasions and is now the Centers for Disease Control and widely known simply as CDC) provided a 4-week training course every year. Only a few WHO staff attended because WHO regional offices were unaccustomed to providing specialized training for newly recruited staff, as most were already experienced in the work that they were expected to do. In any event, by 1970, because of the early interruption of smallpox transmission in western and central Africa (see Chapter 17), the CDC course had so changed in character as to be of limited value for those engaged in the early phases of an eradication programme. WHO had provided specialized training at malaria eradication centres, but smallpox eradication was widely perceived as consisting in little more than mass vaccina-

tion, for which little specialized knowledge was thought to be needed. A WHO-conducted interregional training course was not available as an option because most regional offices did not wish to incur the expense of sending new advisers to Geneva for briefing. Most new staff therefore took up their positions with a briefing of a week or less in their respective regional offices, provided that there was a smallpox adviser in the region to brief them and that he was not then on duty travel. Not until 1974, when the number of international staff increased substantially, did WHO begin to provide organized training programmes for its staff. These were conducted at national level, first in India and then in Bangladesh and Somalia, concurrently with their large-scale intensified programmes.

Other methods were used to educate and orientate newly recruited staff. It was believed and subsequently confirmed that the clinical characteristics of smallpox could soon be learned after arrival in the country. For this purpose, the following were available: the WHO Handbook; a 4-colour, 8-page printed folder showing pictures of smallpox in African patients and describing the course of the disease (1969); sets of teaching slides showing smallpox in African patients (1969) and Asian patients (1971); and a large wall chart showing the appearance of smallpox and chickenpox rashes at various days after the onset of the disease (1970).

The epidemiological principles underlying proper surveillance and containment proved more difficult to convey. Many different approaches were used, beginning with the instructions provided in the WHO Handbook. Later, two case histories with syllabuses were developed, one dealing with techniques for the investigation and control of an outbreak (SE/71.1) and the other with surveillance-containment measures to be taken in an area with a population of about 2-3 million (SE/72.7). (The latter was adapted for use as a case history by the Harvard School of Business Administration.) On-site tutorial training was provided by WHO Headquarters and some regional smallpox eradication programme staff, and periodic intercountry meetings were structured to emphasize surveillance-containment methods and to illustrate approaches. Reports and materials distributed every 2-3 weeks in the so-called "biweekly mailing" (see below) also proved useful. All these efforts, however, fell short of what was required, as was shown by

the length of time required to implement surveillance-containment programmes in most areas and the fact that some African countries were never fully successful in doing so.

Difficulties in communicating with staff working in the field also hampered efforts to develop expertise and solve problems. All communications from Headquarters had to be routed through the appropriate regional office, logically the principal point of contact for the countries in that region. Where there was a full-time smallpox adviser and the region comprised few countries—South-East Asia, for example—reasonably close contact with field staff and programmes in the countries was possible. Where there was no full-time adviser and the countries in the region were numerous, as in Africa, communications were difficult and special measures were necessary. The nature of the problems may be illustrated by the fact that, if a letter was sent from Geneva to the regional office inquiring about the status and needs of a national programme, it was usually necessary for a regional adviser to prepare a special letter for the signature of one of his superiors or the regional director. After drafting and revision, the letter would then be sent to the WHO representative, who would contact either the WHO smallpox adviser or the national health authority. When the information had been obtained, a letter of reply would be prepared and the procedure repeated in reverse. Since the mail was slow and unreliable almost everywhere, it was exceptional to receive a reply to a query from Geneva in less than several months, if it was received at all.

This problem was overcome to some extent by arranging for copies of important correspondence and telex messages to be sent direct from a country to Geneva, and for Headquarters staff, likewise, to send a copy of the reply to the country, the original being sent to the regional office as prescribed. This was of crucial importance in many instances, for example, in dealing within days with an acute shortage of vaccine in Uganda at a time when a telex message "through the proper channels" took 8-9 weeks. Although this approach violated the prescribed procedures, field staff frequently noted that the immediate responsiveness of Headquarters staff to their requests and queries played an important role in sustaining morale and giving impetus to the programme.

Up to the end of 1967, WHO smallpox eradication programme staff throughout the world numbered less than 30. Additional WHO staff were required as national programmes began but recruitment proceeded slowly, the ability and dedication of recruits varying greatly. Except for those who were assigned to Geneva or were members of an interregional team, recruitment and selection were the responsibility of the regional offices, whose personnel services operated independently of Headquarters. Headquarters smallpox eradication staff endeavoured to assist the regional offices in identifying suitable candidates through personal contacts and the screening of applications received in Geneva, but proposals at first were as often ignored as accepted. An especially discouraging episode was the assignment by one regional office of a particularly well qualified candidate to an entirely different programme after months of work by Headquarters smallpox eradication staff to recruit him to WHO for work on smallpox eradication.

Because of the problems, such impetus as the programme possessed during its first few years was provided by a very small number of qualified WHO staff, the staff of the programme conducted with United States assistance in western and central Africa, and national staff. Among the WHO staff were Dr Pierre Ziegler, who worked in Zaire; Dr Celal Algan in Rwanda; Dr Karel Markvart in East Pakistan; Mr Henry Smith in Kenya; Mr Leo Morris in Brazil; Dr Jacobus Keja in the Regional Office for South-East Asia; and Dr Ehsan Shafa in the Regional Office for the Eastern Mediterranean. Eventually, however, a reasonably satisfactory collaborative relationship with respect to recruitment evolved between Headquarters and two of the four Regions concerned.

At first, many international staff were transferred from other projects which were not progressing well or in which the staff had proved unsuitable. Over a number of years, some of the less effective and less industrious staff were transferred by WHO to yet other programmes or did not have their contracts extended. A stated policy of the programme that all smallpox eradication staff should spend at least one-third of their time in the field facilitated this weeding-out process, the policy being monitored, where necessary, by review of daily tour diaries.

Especially helpful in the recruitment of more capable staff were senior epidemiolo-

# CHICKENPOX

Stages  
of rash

If smallpox is suspected notify the health authority immediately. Isolate the patient and vaccinate all contacts.

## smallpox

- The smallpox patient becomes ill between 7 and 17 days after close contact with someone who has the disease
- The patient has fever and does not feel well for 2 to 4 days before a rash appears
- The poxles are most numerous on the face, arms and legs
- Poxles are usually present on the palms and soles
- Scabs begin to form 10 to 14 days after the rash appears
- Scabs fall off 14 to 28 days after the rash begins

smallpox - distribution of the rash

## chickenpox

- The chickenpox patient becomes ill between 14 and 21 days after close contact with someone who has the disease
- The patient usually has no symptoms until the rash appears
- The poxles are most numerous on the body
- Poxles are seldom present on the palms and soles
- Scabs begin to form 4 to 7 days after the rash appears
- Scabs fall off within 14 days after the rash begins

chickenpox - distribution of the rash

**Plate 10.10.** The right-hand portion of the poster in Plate 10.9. The text and drawings at the bottom gave simple indications by which to distinguish the signs and symptoms of smallpox from those of chickenpox.

**Plate 10.11.** The front and back of two versions of the shirt-pocket-size WHO smallpox recognition card produced in 1972. They were first used in India, and tens of thousands were eventually distributed to search workers throughout the subcontinent. The first version (upper pictures) was selected to portray a patient with relatively mild smallpox; it is a reduced version of the larger card shown in Plates 10.29 and 10.30.

**Plate 10.12.** **A:** Zdeněk Ježek (b. 1932) was attached to the WHO Regional Office for South-East Asia in 1972, working for smallpox eradication in India. He later served in Somalia, before joining the Smallpox Eradication unit at WHO Headquarters in 1980 and succeeding Arita as Chief of the unit in 1985. **B:** Ehsan Shafa (b. 1927) was the smallpox eradication adviser in the Eastern Mediterranean Region of WHO, 1967-1971, and then served with the Smallpox Eradication unit at WHO Headquarters until 1977.

gists from a number of countries who were interested in the programme and aware of its demands and who screened and referred former students and colleagues. Such epidemiologists included Dr Karel Raška, Czechoslovakia; Dr Jan Kostrzewski, Poland; Dr Holger Lundbeck, Sweden; Dr Viktor Zhdanov, USSR; and Dr Paul Wehrle, USA. From early in 1972, when smallpox epidemics unexpectedly occurred in Bangladesh, until 1977, Dr David Sencer, then Director of CDC, made available the services of 5 full-time CDC staff, and from 1974, the High Institute of Public Health in Alexandria, Egypt, provided a number of faculty members and former students.

As the programme progressed, the number of capable staff with field experience gradually increased, and those who had successfully worked in their own national programmes were recruited for service in other countries. These included staff from Afghanistan, Bangladesh, Brazil, India, Indonesia, Nepal, Pakistan, the Sudan, Togo and Yemen.

International volunteers contributed significantly, both while serving as such and subsequently when recruited as consultants or staff. Arranging such volunteer support was difficult, however, because WHO policy until the mid-1970s was that volunteer assistance had to be arranged strictly between recipient and donor governments, WHO staff

not being allowed to assist in the process. Unofficial contacts and private correspondence, however, served to facilitate the assignment of United States Peace Corps volunteers in Afghanistan, Ethiopia and Zaire; volunteers from Japan and Austria, who served in Ethiopia; and British volunteers from OXFAM (a British private charitable organization), who worked in India and Bangladesh. Regrettably, an offer by Sweden, in 1970, to assign young medical officers at Swedish government expense to WHO itself had to be rejected by the Organization for policy reasons.

Until 1973, international staff assigned to a country rarely numbered more than 1-4, with the exception of large countries and those with an especially difficult terrain and a shortage of national personnel—Afghanistan, Bangladesh (from 1972), Ethiopia, Nigeria and Zaire. From 1973 onwards, increasingly large numbers of international staff worked in Bangladesh and India and later in Ethiopia and Somalia as more funds became available and efforts were intensified to achieve eradication in the shortest possible time. Throughout the course of the global programme, however, international staff of all types at any given time never numbered more than 150. In all, 687 WHO staff and consultants from 73 different countries eventually served in the programme for periods

ranging from 3 months to more than 10 years; approximately 125 others served with the programme under bilateral agreements. Most of the staff were less than 40 years of age and some less than 30, youth being an advantage where living and travelling conditions were difficult.

Although international staff were few, they played an important role in sustaining national government support, providing programme continuity where national leadership changed for political or other reasons, and expediting the transfer of new techniques from one programme to another. In retrospect, it may be said that few national programmes achieved much success where international staff were of poor quality, but national staff, given the necessary support and encouragement, showed themselves to possess a skill and dedication which equalled and often exceeded those of the international advisers.

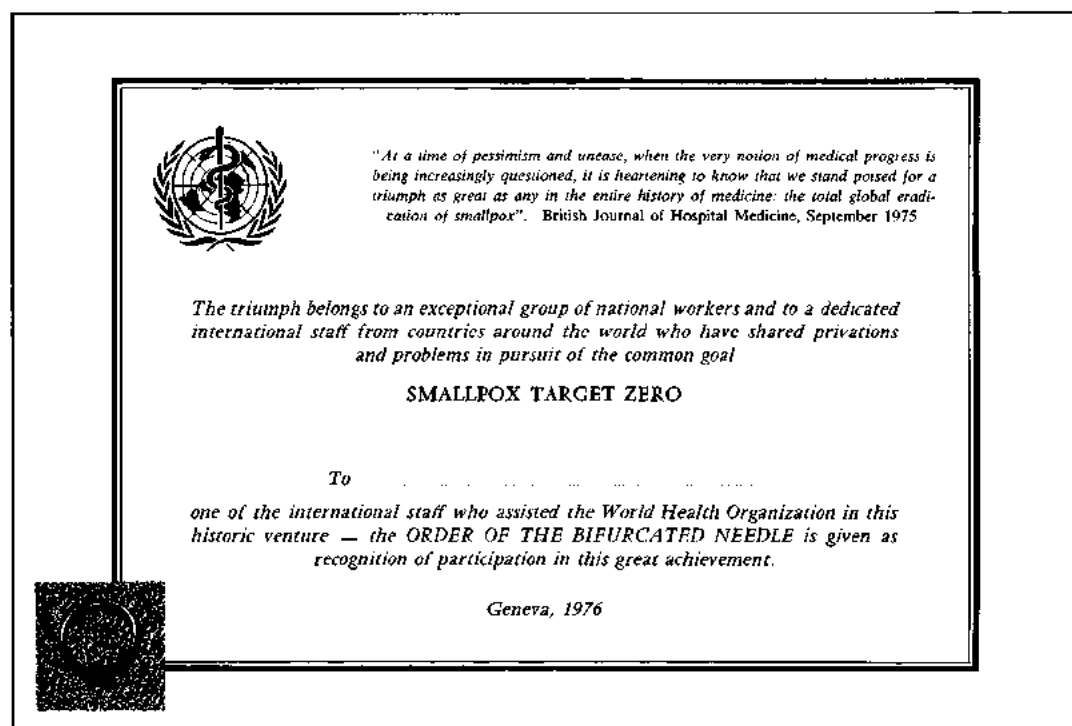

### **OBTAINING NATIONAL AGREEMENTS TO UNDERTAKE PROGRAMMES**

Although commitments assumed by governments by virtue of votes in favour of resolutions at the World Health Assembly were morally binding, WHO could not force governments to undertake programmes. Thus, although the Intensified Smallpox Eradication Programme was unanimously approved by the Health Assembly, only certain countries were, in fact, then prepared to undertake eradication programmes—much as had been the case during the period 1959–1966. Some lacked resources, while others considered that other health problems were of higher priority. Universal participation was essential if the programme was to succeed but, as described earlier, WHO's role in actively promoting and advocating a particular programme in all countries was an unaccustomed one. Malaria eradication was the only other programme in which this had been attempted but, in that programme, the necessary but substantial additional national costs had distorted health allocations, and the extent to which its secondary objective, the improvement of basic health services, had been attained had fallen far short of expectations. Mindful of this experience and doubtful of the feasibility of smallpox eradication,

the Director-General cautioned his regional directors, at a meeting immediately after the 1966 World Health Assembly, against appearing to impose a smallpox eradication programme on any country. Thus, in 2 regions, Africa and South-East Asia (unfortunately also those most seriously affected by smallpox), the regional directors did not initially promote smallpox eradication programmes, assistance being provided only to countries specifically requesting it. In the Region of the Americas and the Eastern Mediterranean Region, however, eradication programmes were actively promoted from the beginning.

In the Americas, smallpox eradication was not a new objective, a regional eradication programme having been in existence since 1950 (see Chapter 9). A Regional Adviser on Smallpox Eradication, Dr Bichat Rodrigues, was appointed in 1966 to coordinate the effort, and Brazil, the only endemic country, committed itself to a national smallpox eradication programme employing what were then the new jet injectors (see Chapter 12). Vaccination campaigns in many other countries in South America began soon thereafter. In the Eastern Mediterranean Region, there were then 3 endemic countries—Ethiopia, Pakistan and Yemen—and there, also, an adviser on smallpox eradication, Dr Shafa, was immediately appointed. He successfully promoted programmes in Pakistan, Yemen and other countries of the region although, for reasons beyond his control, he was unsuccessful in Ethiopia, in which a programme did not begin until 1971 (see Chapter 21).

In the South-East Asia Region, the Regional Director shared the Director-General's belief that eradication represented an unattainable goal, given the stage of development of national health services (see Chapter 9). Responsibility for smallpox eradication was assigned to a 2-man intercountry advisory team which dealt with other communicable diseases as well and whose budget for travel was small. Little was done in the Region until Dr Herat Gunaratne was elected Regional Director in 1968; coming from Sri Lanka, a country which had eliminated endemic smallpox decades before, he saw no reason why this could not be achieved elsewhere. He therefore made the intercountry team, Dr Keja and Dr Louis Grem-liza, responsible solely for smallpox eradication and, from the time of his election, played

**Plate 10.13.** The contribution of the international staff who participated in the eradication of smallpox was given sincere if informal recognition by their promotion to the mock "Order of the Bifurcated Needle", accompanied by an official-looking certificate and a hand-made lapel pin. The pins (inset) were fashioned from bifurcated needles in the form of an "O" to symbolize "Target Zero", the objective of the programme.

an active role in encouraging national programmes. The response was generally enthusiastic and within a year effective programmes were in progress in all endemic countries of the region except India, where the programme started later (see Chapter 15).

In the African Region, by late 1966, a number of countries had already committed themselves to national smallpox eradication programmes. These included the 20 countries of western and central Africa which were participating in the smallpox eradication and measles control programme being carried out with the assistance of the USA; Zambia, which had begun a national vaccination campaign in 1966 because of epidemic smallpox; and Zaire, whose WHO-supported activities were then coordinated by Geneva Headquarters. The other African countries did not officially express any interest in 1966 and early in 1967. This was disturbing to the staff in Geneva, but also puzzling because funds were then available to meet all the costs of the programmes except salaries for the comparatively small number of national personnel who would be required. Because

WHO was prepared to provide vaccine free of charge and because many countries already employed smallpox vaccinators, it was actually cheaper for most of them to participate in the eradication programme than to continue smallpox control activities. They failed to express interest, as was later discovered, because no effort was made by the Regional Office to encourage programmes, acquaint national authorities with the programme's budgetary implications, or indicate the amount of support which could be provided by WHO; instead, the national authorities were expected to request WHO's assistance on their own initiative. The WHO representatives in the countries, as well as Ladnyi, then intercountry smallpox adviser for East Africa, were informed of this policy in September 1966. In the spring of 1967, the problem was resolved fortuitously when a member of the Headquarters Smallpox Eradication unit was given permission to visit several of the countries for the purpose of gathering information for the Director-General's report to the 1967 World Health Assembly. Although he was forbidden to

suggest to any country that a programme should be undertaken, he made the health authorities aware of the nature of the programme and the resources available and, within weeks, letters requesting WHO assistance were received from almost all of them.

By the summer of 1969, smallpox eradication programmes had begun in all the endemic countries in Africa except South Africa, Southern Rhodesia (now Zimbabwe) and Ethiopia. WHO then had no official relations with the first two of these, South Africa having ceased to participate in the Organization and Southern Rhodesia being technically still a colony of the United Kingdom, although it had unilaterally declared independence. Visits by WHO staff were not permitted and little information could be obtained about the status of smallpox or their programmes. However, neither was thought to represent a serious impediment to eventual global eradication because neither officially reported many smallpox cases and their health services were comparatively well developed. Both began special programmes in 1970 (see Chapter 20), stimulated largely by reports in the *Weekly epidemiological record*, which described excellent progress in smallpox eradication elsewhere in Africa but noted the lack of information from South Africa and Southern Rhodesia. The third country, Ethiopia, although in Africa, was served (until late in 1977) by the Regional Office for the Eastern Mediterranean and presented quite a different problem. Smallpox was widely endemic and health services were few, but malaria eradication staff and their international advisers, fearing that another programme would be a harmful distraction, persuaded government officials to refuse to discuss with WHO the implications of a smallpox eradication project. Not until late in 1969 did the government permit Henderson and Dr Shafa to visit the country. At that time, Ministry of Health officials declined to participate but the Emperor himself, who by chance had heard about the programme, intervened to commit the government and, in 1971, the last of the programmes in the endemic countries began (see Chapter 21).

Thus, although many countries needed to be encouraged and persuaded to undertake smallpox eradication programmes, these had, in fact, been initiated in all endemic countries within 5 years of the 1966 decision. It was quite another problem to ensure that the

various governments were sufficiently committed for eradication of the disease to be achieved.

### SUSTAINING GOVERNMENT INTEREST AND COMMITMENT

A continued high level of interest and support for the eradication programme was difficult to sustain in many countries, just as it was in WHO. Changes in governments and/or senior health personnel were often associated with differences in priorities and in levels of commitment. Smallpox was but one of many problems competing for attention and resources and, in countries in which the mild variola minor form was prevalent, it was understandably not of high priority. After the last known cases had occurred, resources were particularly difficult to obtain from recently endemic and donor countries, as well as from WHO itself, in order to continue surveillance and thus permit certification.

#### Role of the World Health Assembly

The World Health Assembly, convened each year for a period of several weeks, was a particularly important opportunity for promoting and sustaining interest in the smallpox eradication programme. Senior health officials from all Member States attended and, in addition to reviewing the proposed WHO budget, discussed the Organization's overall programme of work as well as specific programmes, such as that for smallpox eradication. During the debate, delegates frequently described what their own countries were doing, some asked questions of a technical nature and others took the opportunity to announce voluntary contributions. The Intensified Smallpox Eradication Programme, if included as an agenda item, might be discussed for 2-4 hours or more. Such a discussion served to focus the attention of health officials on the subject, and important principles—such as the role of surveillance and the need to use only freeze-dried vaccine—could be emphasized by the Secretariat. It also enabled government officials to hear what were often heartening or optimistic reports of progress in other countries, causing them to reexamine their own programmes. If, however, smallpox eradication was not included in the agenda as an item for

debate, it could still be discussed when the overall programme of the Organization was considered, but it was unusual for many delegates to prepare themselves to speak on the topic and the debate was usually brief.

Because the Health Assembly had identified smallpox eradication as a priority programme of the Organization and it had been on the agenda each year from 1959 to 1967, the Smallpox Eradication unit staff assumed that the topic would continue to be an annual subject for debate on which the Director-General would provide a special report to the Health Assembly. From 1968 onwards, however, it began to be omitted from the provisional agenda. The resolution on smallpox eradication adopted by the Twentieth World Health Assembly (1967), called only for the Director-General "to report further" on smallpox eradication to the Executive Board and the Health Assembly. "Further" was interpreted to mean at some time in the future and the topic was omitted from the provisional agenda of the Twenty-first World Health Assembly (1968), an action which was reversed at the request of the USSR. Resolutions adopted at the 1969, 1971, 1972, 1976 and 1977 Health Assemblies called specifically for special reports to each of the subsequent ones and for smallpox eradication to be included in their agendas. In the other years until 1977, when transmission was interrupted, smallpox eradication was the subject only

of a brief general discussion in the context of the overall WHO programme. A report by the Director-General was nevertheless prepared and kept in readiness in case one was requested by delegates. To it was attached a comprehensive review of the programme's progress and status that was published twice a year in the *Weekly epidemiological record* to coincide with the January session of the Executive Board and with the Health Assembly. Although the report was not to be distributed unless requested by delegates, the interest expressed, particularly by two delegates, one from the USSR and the other from the USA (Dr Dmitriy Venediktov and Dr Paul Ehrlich, Jr, respectively), ensured that it was distributed and the programme discussed.

### Surveillance Reports

Regularly published surveillance reports, both international and national, were an essential component of the surveillance process and, as experience had demonstrated in other disease control programmes, were also important in stimulating and sustaining the interest of those concerned with the programme. Such reports documented the numbers of cases reported weekly by administrative area, charted trends in incidence and in the progress of the programme, and discussed alternative strategies and tactics in

**Plate 10.14.** Two delegates to the World Health Assembly and members of the Executive Board of WHO who were strong advocates of smallpox eradication. **A:** S. Paul Ehrlich Jr (b. 1932), Surgeon General of the United States Public Health Service. **B:** Dmitriy D. Venediktov (b. 1929), Deputy Minister of Health of the USSR.

different areas. The first WHO surveillance reports on smallpox eradication were issued in September and December 1967, and from May 1968 onwards, they began to be published every 2-3 weeks in the *Weekly epidemiological record*, some 5000 copies being distributed to health officials and others throughout the world. The system was not established without difficulty, however, as is discussed later in this chapter in the section entitled "International surveillance reports". The WHO Regional Office for South-East Asia also issued surveillance reports from 1974 onwards, and national surveillance reports were published monthly and sometimes weekly or every 2 weeks in a number of countries.

In addition to providing information to widely scattered health staff, the reports also served to inform both public officials and the press, sometimes with unexpected consequences. When, in Brazil, Ethiopia and India, for example, better surveillance and improved reporting were accompanied by marked increases in the numbers of notified cases, national officials and the press expressed concern, and even alarm, although the increases were attributed, at least in part, to better reporting. Greater political commitment and increased resources soon followed. In other countries, interest in the programme grew significantly when national officials read of more satisfactory progress being made in other countries, some of which they believed to have health services inferior to their own.

### Interregional and Intercountry Meetings of Smallpox Eradication Staff

Meetings of senior staff from different national programmes also served to sustain and stimulate the interest of governments and staff while bringing to their notice the new observations which were being made. The WHO Headquarters budget provided for at least one such meeting a year, the venue changing from year to year, as did the participants (Table 10.2). In addition, over the period 1967-1972, CDC supported a yearly conference for the countries of western and central Africa.

The first of these meetings was held in Thailand in 1967 for countries in eastern Asia. At first they were largely devoted to the presentation of reports on national programmes by the respective national directors; over time, their nature gradually changed and each country was asked to present papers illustrating specific findings, the outcome of particular strategies and interesting new approaches. The ensuing discussions made it possible to determine whether the observations made in a particular national smallpox eradication programme were of relevance to the others. Most of these reports were distributed by WHO to all concerned with smallpox eradication through the special WHO/SE, SE and SME series of mimeographed documents (see References: WHO documents); some were also published in the medical literature.

Table 10.2. WHO seminars and meetings on smallpox eradication, 1967-1978 (excluding those associated with certification of eradication)

Date	Country in which held	Participants <sup>a</sup>
December 1967	Thailand	13 countries of South-East Asia, Eastern Mediterranean and Western Pacific Regions
November 1968	Zaire	11 countries of southern and eastern Africa
May 1969	Nigeria	18 countries of western and central Africa (joint seminar with CDC)
November 1969	Pakistan	11 countries of Eastern Mediterranean and South-East Asia Regions
December 1970	India	11 countries of South-East Asia, Eastern Mediterranean and African Regions
September 1972	Ethiopia	4 countries of eastern Africa
November 1972	India	5 countries of South-East Asia Region
November 1972	Pakistan	4 countries of Eastern Mediterranean Region
September 1973	Ethiopia	Ethiopia and WHO Eastern Mediterranean Region smallpox eradication advisers
November 1973	Pakistan	Pakistan and WHO Eastern Mediterranean Region smallpox eradication advisers
August 1974	India	Bangladesh, India and Nepal
January 1976	Nepal	6 countries of South-East Asia Region
March 1977	Kenya	4 countries of eastern Africa
September 1977	Kenya	5 countries of eastern Africa
April 1978	Kenya	5 countries of eastern Africa and the Eastern Mediterranean Region

<sup>a</sup> Participants included national programme staff and WHO smallpox advisers and other smallpox eradication staff from the regional offices and WHO Headquarters. Advisers from the regional offices in the 4 endemic regions were invited to all meetings from 1967 to 1970 and to the 1972 meeting in India.

**Plate 10.15.** Participants in the first interregional seminar on smallpox eradication held in Bangkok, Thailand, 11-16 December 1967. Left to right, front row: A. M. Khan (Pakistan), A. R. Rao (India), M. K. Singh (India), S. A. Mallick (Pakistan), D. A. Henderson (WHO), E. Na Bangxang (Thailand), S. Falkland (WHO), J. J. Dizon (Philippines), I. F. Setiady (Indonesia), U. Thaug (Burma); middle row: Z. Rahman (Pakistan), C. Rubinstein (WHO), C. H. James (United Kingdom), J. Singh (Malaysia), K. S. Ramakrishnan (India), G. P. Nikolaevskij (WHO), W. H. Foege (USA), J. Keja (WHO), B. Ignjatovic (WHO), F. G. L. Gremliza (WHO), B. Wirjodipoero (Indonesia), J. C. Pitkin (WHO), Khin Mu Aye (WHO), K. Chatyanonda (Thailand), S. Sornachai (Thailand); back row: C. Patanacharoen (Thailand), A. Prajapati (Nepal), J. S. Copland (WHO), T. M. Mack (USA), G. H. Waheed (Afghanistan), B. Chantasut (Thailand), E. Shafa (WHO), R. M. Lyonnet (WHO), Y. K. Subrahmanyam (India), S. Singh (WHO), P. Tuchinda (Thailand), T. Phetsiriseng (Lao People's Democratic Republic), N. D. Tiep (Viet Nam), P. Kunasol (Thailand), C. Debyasuvarn (Thailand).

The meetings had both tangible and intangible benefits. Several specific changes in programmes can be associated with them: Indonesia's full commitment to smallpox eradication followed the 1967 meeting in Thailand; agreements to grant national surveillance and vaccination teams free passage across specified international borders, a hitherto unprecedented occurrence, followed the 1968 conference sponsored by CDC in Côte d'Ivoire and the 1973 meeting in Ethiopia; and India's decision to adopt the surveillance-containment strategy and to undertake an intensified programme followed the 1972 meeting in New Delhi.

### Use of the Mass Media

The Smallpox Eradication unit staff actively sought publicity for the programme in national and international media, believing that it was important to make what was happening in the programme widely known to potential donors and to those in the endemic countries. For many sectors of

government, this was a natural and logical approach but there was then, both in WHO and in many countries, a reluctance on the part of physicians and other health personnel to meet representatives of the mass media or to use the media except to convey traditional health education messages. The very small staff and limited programme of WHO's Division of Public Information at that time was a reflection of this attitude.

The publication of the semi-annual summaries of progress in smallpox eradication in the *Weekly epidemiological record* provided suitable occasions for press conferences, as did the occurrence of the last cases of smallpox in large countries and the certification of eradication in each of the countries and Regions. Efforts to obtain publicity were not without their embarrassing moments, however, the most awkward occurring on 14 October 1975, when Henderson, then on a visit to New York City, announced at a press conference that 8 weeks had elapsed since the last case of smallpox in Asia and, in view of the extent and effectiveness of surveillance, confidently stated that the last case of variola

major had been seen. Only 4 days later, however, another outbreak was found in Bangladesh (see Chapter 16).

As the programme progressed, increasing attention was given to contacts with the media (see Plate 10.16), particularly as the need for voluntary contributions became more urgent. Geneva was not so important a news centre as New York, in which there were more correspondents from many more countries. Fortunately, WHO maintained a small liaison office at the United Nations in

New York with two public information officers, Ms Joan Bush and Mr Peter Ozorio, who were particularly effective in interesting the media in the programme. Among the unique ideas which they fostered were transatlantic press conferences, one in 1974, in which science writers and correspondents in New York and Washington interviewed Henderson in Geneva, and a second, in 1975, in which science writers in London and Dr Nicole Grasset, the adviser on smallpox eradication in the South-East Asia Region,

**Plate 10.16.** **A:** Lawrence K. Altman (b. 1937), correspondent for the *New York Times*, had been an epidemiologist with the measles control programme in western Africa in 1964–1965. **B:** James Magee (b. 1929) was the public information officer with the Smallpox Eradication unit, 1978–1980. **C** and **D:** Joan Bush (b. 1928) and Peter Ozorio (b. 1928) served in New York as public information officers attached to the WHO Liaison Office with the United Nations.

answered questions from New Delhi, India.

Especially extensive and helpful press coverage was provided twice during the programme—in 1974 and 1978. The first related to epidemic smallpox in India during

1974, the most critical year for smallpox eradication in Asia (see Chapters 15 and 16). In that year, a large number of correspondents, who had come to India to report on the detonation for the first time of an Indian

### Publicizing the Programme

Special issues of the WHO magazine *World health*, stamps and medals served to publicize the programme and its accomplishments. In addition to the special issues of *World health* in 1965 on the theme "Smallpox: Constant Alert" and in 1975 on "Smallpox: Point of No Return", a third special issue was published in October 1972, with the slogan "Smallpox: Target Zero" (Plate 10.18). It coincided with the launching of what was termed the "final phase" which, at that time, was expected to result in eradication by the summer of 1974. As its introduction stated: "The global eradication programme this year, for the first time, extends into every state and province of every country where the disease exists. The final phase of the campaign is beginning." Unforeseen problems, however, resulted in the final phase lasting fully 3 years longer than had been optimistically envisaged.

*World health* featured the subject of smallpox on two other covers—in October 1979, on the occasion of certification of eradication in the last of the endemic countries, and in May 1980 (see Chapter 24, Plate 24.2), when the Thirty-third World Health Assembly accepted the recommendation of the Global Commission for the Certification of Smallpox Eradication that "smallpox eradication has been achieved throughout the world" and that "smallpox vaccination should be discontinued in every country except for investigators at special risk".

Postage stamps and cachets on the theme of smallpox eradication and vaccination were issued by many different governments between 1965 and 1980, as illustrated in Plates 10.19–10.22. The largest number were produced in 1978, the year after the world's last outbreak, in response to a recommendation by the Universal Postal Union to its member governments that smallpox eradication should be a principal philatelic theme. In 1978, too, the United Nations issued special stamps and silver medals in recognition of the achievement (Plate 10.23).

In some countries, stamps echoed the 1965 World Health Day theme of "Smallpox: Constant Alert"; several countries of western and central Africa issued stamps between 1968 and 1972 during the course of the programme for smallpox eradication and measles control, most of which featured pictures of the jet injector; and Guinea, on completion of its WHO-supported smallpox vaccine production laboratory, issued a full set of stamps depicting various stages in the vaccine production process (see Chapter 11, Plate 11.10).

In commemoration of the declaration at the Thirty-third World Health Assembly of the global eradication of smallpox, all delegations were presented with a set of medals as mementos (Plate 10.23); these bore inscriptions in the six official languages of WHO—Arabic, Chinese, English, French, Russian and Spanish.

nuclear device, discovered that the recorded incidence of smallpox was the highest for 20 years and reported this as well. Also in 1974, a series of articles published in the *New York Times* by Dr Lawrence Altman, who was on an extended tour of India and Bangladesh, vividly documented the magnitude of the effort being made and, in turn, stimulated the interest of other publications. The consequent international publicity brought greatly increased and badly needed support for the programme from senior government officials and played an important role in obtaining additional voluntary contributions. In 1978, world-wide press coverage followed the

occurrence of 2 laboratory-associated smallpox cases in Birmingham, England (see Chapter 23) at a time when the Smallpox Eradication unit was having difficulties in persuading laboratories to destroy or transfer their stocks of variola virus. As a result, national governments took a special interest in the matter and compliance followed rapidly throughout the world.

As the goal of global eradication was approached, it was important for a quite different reason to publicize the status of smallpox and its anticipated demise. With the achievement of eradication, it would be possible to discontinue routine smallpox

**Plate 10.18.** The smallpox eradication programme was presented in several issues of *World health*, an illustrated magazine published in many languages by WHO and directed to the general public.

**Plate 10.19.** Postage stamps depicting smallpox eradication activities issued by western and northern African countries between 1968 and 1975. The Libyan stamps at the lower right take up the theme of World Health Day, 7 April 1975: "Smallpox: Point of No Return".

**Plate 10.20.** Postage stamps issued in 1978 by Brazil, Egypt, Iraq, Ireland, Kuwait and Lesotho to celebrate the eradication of smallpox.

**Plate 10.21.** Postage stamps issued in 1978 by Malaysia, Maldives, Mozambique and Nigeria to celebrate the eradication of smallpox.

**Plate 10.22.** Postage stamps issued in 1978 by the Philippines, Senegal, Togo, Tunisia and the United Nations to celebrate the eradication of smallpox.

**Plate 10.23. A:** A proof set, presented to the Director-General of WHO by the United Nations, of sterling silver medals struck to celebrate the eradication of smallpox. The medals were issued on 31 March 1978 in the 5 original official languages of the United Nations in conjunction with the stamps shown in Plate 10.22. **B:** In May 1980, when the Thirty-third World Health Assembly had formally declared the global eradication of smallpox, each delegation to the Health Assembly received a set of commemorative medals in the 6 official languages of WHO.

vaccination as well as the use of international smallpox vaccination certificates. Vaccination was a long-established procedure, however, and it was unlikely to be discontinued unless both health officials and the public were aware of what had been accomplished and had confidence in that achievement. A public information officer, Mr James Magee, was therefore recruited to work full time with the Smallpox Eradication unit in Geneva.

Accounts of the progress made in the Intensified Programme appeared regularly in newspapers and magazines around the world, documentary films were made by the public broadcasting service in the USA and by Japanese television, and many countries issued special stamps; commemorative medals were also struck. Eventually, the press coverage became sufficiently extensive to cause one correspondent to write in *Science* (Wade, 1980) that "WHO has found numerous occasions on which to announce the eradication of smallpox. Another such announcement, issued with some new degree of bureaucratic solemnity, is due to emerge on 12 May. Experts consider that only definitive action by the Nobel Peace Prize committee can break the chain of transmission". However, despite numerous newspaper and magazine articles in countries throughout the world and in publications as diverse as *World health*, *National geographic*, *Reader's digest*, the *Encyclopaedia Britannica* and *Scientific American*, many persons of wide reading suggested to smallpox eradication staff that the achievement was too little known and that more should have been written about it.

### INTERNATIONAL SUPPORT IN CASH AND IN KIND

One of the most difficult problems was that of ensuring adequate international support for the national programmes, whose needs changed, often substantially, from year to year. In the original plan presented by the Director-General to the Nineteenth World Health Assembly in 1966, four sources of support were envisaged: (1) the WHO regular budget which, in 1967, included US\$2.4 million specifically earmarked for smallpox eradication; (2) contributions to the WHO Voluntary Fund for Health Promotion, Special Account for Smallpox Eradication, which the donor could make either in

cash or in kind and which, if desired, could be assigned to a specific project or country; (3) bilateral contributions; and (4) contributions from other international agencies.

The Director-General's report to the Nineteenth World Health Assembly (World Health Organization, 1966b) had forecast a need for US\$48.5 million in international assistance for a 10-year programme (1967-1976), of which one-third was expected to be provided by the WHO regular budget, the balance having to be obtained from the other sources. Ultimately, international assistance from 1967 to 1979, when eradication was certified, amounted to some US\$98 million, of which US\$34 million came from the WHO regular budget.

Of the expected sources of support, funds from the WHO regular budget were of particular importance because they could be used wherever required and for any appropriate purpose, including personnel and travel costs, the purchase of supplies and equipment, and local operational expenses—e.g., for petrol, vehicle repairs and living allowances for national staff. These funds served to complement voluntary contributions and national resources, which sometimes provided only partial support for a country programme. In programmes in western and central Africa, for example, national governments paid staff salaries and the USA provided all other needed resources except funds for the purchase of petrol and for vehicle repairs. Comparatively small sums from the WHO regular budget for "local costs", as they were termed, enabled governments in this region to undertake eradication programmes.

Undesignated gifts of cash to the WHO Special Account for Smallpox Eradication could likewise be used for any necessary purpose and had the further advantage that balances could be carried forward from year to year. Few undesignated gifts of cash were received, however, the contributions until 1974 being primarily in the form of vaccine. During the period 1974-1978, several donors made substantial cash contributions to the voluntary fund, almost all of which were designated for use in specific countries.

Significant bilateral support was provided by the USA and the USSR, the former providing almost all international assistance for programmes in western and central Africa, and the latter supplying very large quantities of vaccine to several Asian countries and to

some in Africa. International agencies other than WHO had been expected to provide substantial assistance but little was received.

Except for the first 2 years of the Intensified Programme (1967-1968), when activities in many countries were only just beginning, the inadequacy of resources presented a continuing problem. Headquarters, regional and national staff expended considerable time and effort in attempts to obtain assistance. Frequently, however, it was found that the available funds were sufficient to sustain activities for only a few months. The difficulties, even as late as 1975, may be illustrated by an estimate prepared in July of that year of the requirements and availability of resources for 1975 and the 2 subsequent years in addition to those provided under WHO's regular budget (Table 10.3).

It had been hoped that, when it became apparent that global eradication was feasible and perhaps within reach, funds would be more readily forthcoming. Even during 1976, however, with known smallpox confined to Ethiopia, the problem did not diminish, as is shown by a memorandum of 17 February 1976 from Henderson to the Director of the WHO Regional Office for the Eastern Mediterranean:

"I concur entirely with you in regard to your appraisal of need for a WHO epidemiologist to be attached to the smallpox eradication programmes in Sudan and Somalia ... I fear that there may be unknown foci ... which may yet cause real problems ... However, I'm very concerned about our funding position ... Frankly, at this time, we simply don't have the money to fund the Ethiopian programme beyond April or May and, at the same time, funds for Bangladesh will be exhausted at the end of March. One would have expected all sorts of support at this time but we are simply not getting it."

### The WHO Regular Budget

Funds from the WHO regular budget were an important component of international assistance but it was difficult to apply them optimally in the context of ever-changing global needs. Their allocation by WHO Region and by country should ideally have taken into account both relative need and the global strategy, but this was difficult given WHO's decentralized structure and administrative procedures.

The WHO budget process was best suited to the support of a diverse array of national

Table 10.3. Estimated requirements and available resources as at July 1975, in addition to those provided under the WHO regular budget, 1975-1977 (US\$)

Year	Amount needed	Available	Deficit
1975	1 975 000	1 445 000	530 000
1976	1 560 000	345 000	1 215 000
1977	1 450 000	345 000	1 105 000

projects, which were usually small and had financial requirements that were reasonably predictable from year to year. The Director-General's annual budget, developed over a 2-year period, was a composite of proposals prepared separately by regional directors and Headquarters units and based, in part, on requests for assistance received from countries. Each regional director drew up a detailed budget specifying personnel and other costs for each project in each country and in the regional office. These project proposals were usually not reviewed by the relevant technical units at Headquarters, which similarly submitted detailed budget proposals of their own, broken down by permanent staff and consultant costs, as well as proposed expenditures for travel, meetings and other items. Following a review of the proposals by the Director-General and the assistant directors-general, an overall proposed programme and budget for the entire Organization was set out in detail for consideration by the Executive Board at its January session and by the World Health Assembly, which was usually convened in May—7 months before the beginning of the next financial year. The Smallpox Eradication unit had no indication as to the total allocations available for smallpox eradication each year until the budget volume was distributed.

The budget was almost invariably approved by the Health Assembly as presented, after which each regional director could transfer WHO regional resources from one project to another as need and opportunity presented. Funds could be transferred from one region to another only by the Director-General, but such transfers were seldom made.

In 1967, more than 90% of all the funds voted for smallpox eradication by the Health Assembly were allocated by the Director-General to the 4 regions in which endemic smallpox was then present (Table

10.4), only a small amount (about 8%) being provided to support Headquarters or inter-regional activities.

Because of the nature of the budget process, the Smallpox Eradication unit decided that the best way of achieving the optimum allocation of resources was through close collaborative planning with regional office staff. If this could be achieved, it was believed that a consensus on needs and priorities could be reached which would be reflected in annual budgets, and it would be possible to provide up-to-date information to regional directors so that transfers of funds could be made where required. Thus, each year, a planning meeting was scheduled which was attended by the officer responsible for smallpox eradication in each regional office together with senior Smallpox Eradication unit staff. Although it was usually possible to reach a consensus as to priorities and allocations of resources, the subsequent execution of agreed plans ranged from excellent to indifferent.

During the first 2 years of the Intensified Programme, the full utilization of appropriated funds was a major concern. At the Nineteenth World Health Assembly, in 1966, a number of delegates had proposed a budget of US\$1 million for smallpox eradication, since they doubted whether the Organization could fully utilize US\$2.4 million. Although the Director-General had assured them that the larger amount could be well used, this was, in fact, not easily accomplished. Before funds could be obligated, country plans and lists of the supplies and equipment needed had to be drawn up. With full-time advisers for smallpox eradication in only 2 of the WHO regions, and those not the most seriously affected, the task was not easy. Yet, if the funds were not fully expended, it would reflect poorly on the Organization. In 1967 and 1968, a lengthy correspondence was carried on with each of the WHO regions concerned, analysing and reanalysing budgets and obligations and repeatedly urging the regions to develop agreements and obligate funds as soon as possible.

The full obligation of allocated funds would have been facilitated by the procurement of a reserve fleet of vehicles, to be dispatched as they became needed by countries. This was a practice followed by UNICEF and one which would have alleviated serious delays in starting programmes, which

Table 10.4. Director-General's budgetary allocations for smallpox eradication for 1967 and estimated actual expenditure (US\$)

Region	Budget allocations for smallpox	Estimated actual expenditure
Africa	658 428	460 090
Americas	629 000	742 063
South-East Asia	815 030	295 281
Europe	0	0
Eastern Mediterranean	246 706	573 999
Western Pacific	2 000	55 831
Headquarters and Interregional	210 640	268 552
Total	2 561 804	2 395 816

were often caused by 12-18-month delivery times for vehicles. A proposal to this effect, however, was not accepted.

In 1967, plans were quickly developed in the Region of the Americas and the Eastern Mediterranean Region but far less was accomplished in Africa and South-East Asia. As the year progressed, it became apparent that the funds committed in these latter regions would fall substantially short of those allocated. This problem, however, was solved in a manner that served indirectly to provide the Smallpox Eradication unit with added discretionary resources for emergency needs. Towards the end of 1967, the Regional Director for South-East Asia was persuaded to release funds allocated for use elsewhere and the Director-General approved the transfer. Some were transferred to the Regions of the Americas and the Eastern Mediterranean and some were used for the purchase of large numbers of the new bifurcated needles and jet injectors. The subsequent ability to dispatch bifurcated needles and jet injectors (as well as vaccine) promptly to countries in need was of great help in carrying out programme activities. The Regional Director for Africa chose not to release his unobligated funds and, in December, at the end of the financial year, they were returned to Headquarters. Fortunately, however, it proved possible to recover them for the programme, thanks to the Division of Budget and Finance. Cash contributions to the WHO Voluntary Fund for Health Promotion's Special Account for Smallpox Eradication had not been large, but a moderate sum had accumulated by 1967. In that year, virtually all these funds had been spent on travel, consultants and training materials. The unobligated funds from the African Region were used to cover these

expenditures, and the cash balance in the special account was restored and carried forward to the following year. Almost every year thereafter unobligated funds from the regions enabled the cash balance in the special account to be largely restored, thus providing a small but immensely valuable cash reserve to supplement the meagre discretionary funds otherwise available for smallpox eradication through Headquarters accounts.

By 1969, most countries had begun eradication programmes and the problem of lack of funds replaced that of utilizing budgeted allocations. As Henderson wrote to the regional smallpox adviser in the Americas (21 February 1969):

"I am concerned about the problem of money this year for I am afraid we will be very hard pressed indeed. We could use substantially more in the African Region; the Eastern Mediterranean Region has requested some additional [funds] ... and the South-East Asia Region, if the Indian programme accelerates as expected, could use everything we have. I am afraid the honeymoon is over with respect to finances."

It was also pointed out that Brazil, the only endemic country in the Region of the Americas, had already received substantial resources, including funds released in 1967 by the South-East Asia Region, and it was suggested that the Region of the Americas might reciprocate by releasing some of its funds for use elsewhere. However, such transfers of funds were not customary and this proposal was rejected, as were similar subsequent ones.

To achieve a more appropriate distribution of funds, the next best approach seemed to be to attempt to change the regional allocations from year to year to reflect more accurately the relative balance of needs in the different regions. The first allocations, in 1967, had necessarily been arbitrary ones, since it had not been possible at that time to make accurate estimates of need by region. Up to 1970, the allocations remained essentially unchanged but, by then, it was increasingly apparent that far less would be required in the Americas during future years but far more in Asia and Africa and that a reapportionment based on longer-term requirements was needed. Throughout 1970, Smallpox Eradication unit staff worked closely with those in the regions to reach a consensus on future needs. Towards the end of the year, however, the unit was informed that proposals based on

these analyses would not be approved by the Director-General. Although the exercise had proved futile, it was hoped that it might still be possible at least to reduce the allocation to the Americas and to increase it in other regions. In a memorandum (dated 30 December 1970) to his Assistant Director-General, Henderson pointed out:

"Plentiful funds are available in the Region of the Americas as confirmed in discussions in Washington during December ... all concerned feel confident that smallpox transmission in the Americas will be interrupted in 1971. It is proposed that smallpox eradication funds be used to strengthen surveillance activities [in the Americas] ... However, even if gilt-edged support is provided to this enterprise, it is agreed that it would be difficult to expend more than \$250-300 000 per year [of a budgeted US\$569 000]."

The proposed change in allocation was discussed with the Regional Director for the Americas, who agreed with the budget analysis but pointed out that he needed more funds for malaria eradication and asked for some sort of trade-off so as to maintain his regional budget at a more constant level. The Director-General decided, however, not to alter the regional allocations for smallpox eradication for 1971 and, from 1972, the practice of identifying a specific allocation for smallpox eradication was discontinued. This ended the efforts to develop plans for the better deployment of funds from WHO's regular budget. After 1971, it was no longer required that a prescribed minimum amount should be spent on smallpox eradication; the regional directors allocated funds from their overall allotments on the basis of their sense of the programme's priority in relation to the other needs in their regions.

When inflation is taken into account, as was customary each year in preparing WHO's overall budget, the Organization's annual expenditures for the programme up to 1976 were close to the appropriation of US\$2.4 million originally approved by the Health Assembly in 1966 (Table 10.5). However, as the number of endemic countries decreased, increasing problems were encountered in obtaining the support necessary to complete the programme and to permit certification, as is shown by a memorandum of 6 January 1975 from Henderson to the Director-General:

"We may face some difficult questions at the Executive Board in regard to the smallpox budget

which we should be prepared for. In November, a special appeal was made by the Director-General for additional funds for the smallpox programme. The importance of the programme and the high priority given to it by the Organization was emphasized. Only \$2.1 million of the \$3.3 million requested has so far been received but we know of at least five additional countries which have indicated that additional support might be forthcoming.

"The difficult problem about which questions will almost certainly be forthcoming is why the Organization cut the smallpox allocations (by 29%) if it accords the programme such high priority and is asking for special donations. The budget cuts are evident not only in the Regions but also at Headquarters.

"As the first knowledge which I had in regard to the budget levels was when I received Official Records No. 220 [Proposed Programme and Budget for 1976-1977], I find it difficult to contrive a suitable answer which might be proposed. And yet, an inappropriate response could be most damaging, as I'm sure you would agree."

Questions were asked by the Board but the budget was not changed.

### Other Types of Assistance to Programmes

As has been mentioned earlier, it was expected that two-thirds of the total costs of the smallpox eradication programme would be met by international agencies other than WHO and by voluntary contributions to governments or to the Special Account for Smallpox Eradication in the WHO Voluntary Fund for Health Promotion. In view of the level of support for smallpox eradica-

tion during 1959-1966 (see Chapter 9), this originally seemed to be an unrealistic expectation, but such contributions eventually amounted to US\$66.9 million over the period 1967-1979 (Table 10.6).

The different types of contribution are, for the most part, considered together in this section, since it is somewhat arbitrary to identify some as bilateral contributions, some as support to the Special Account for Smallpox Eradication and some as contributions by other international organizations. For example, the substantial cash contributions made by Denmark, Norway and Sweden to programmes in Bangladesh and India during 1974-1977 were provided through the special account for administrative convenience but were a part of the bilateral assistance funds already allocated for use in these countries. Similarly, support from two United Nations organs, the United Nations Emergency Operation (UNEO) in Bangladesh in 1972 and the Office of the United Nations Disaster Relief Co-ordinator (UNDRO) in Somalia in 1977, consisted of supplies and equipment provided by national governments in response to emergency appeals rather than of funds from the established budgets of these organs.

Throughout the programme, an effort was made to account for and place a cash value on the support provided by different agencies. The data as presented, however, suggest a greater precision and completeness in accounting than is, in fact, the case. Many of the contributions were in kind rather than in cash. When a contribution was provided through the Voluntary Fund for Health Promotion, the donor was responsible for

assigning a cash value to it but different donors assigned different values to the same product. For example, most vaccine was valued at US\$10-16 per 1000 doses but values as high as US\$256 per 1000 doses were assigned by some donors. The average value for all vaccine contributed worked out at US\$17 per 1000 doses, although estimates of the actual costs of vaccine production in the industrialized countries in the early 1970s were in the range of US\$30-40 per 1000 doses.

It may be noted that in several instances the amounts in Table 10.6 are different from those recorded by the Global Commission for the Certification of Smallpox Eradication in Annex 16 to its Final Report (World Health Organization, 1980). The differences are the consequences of adjustments made in the light of more recent information. In addition, Annex 16 included the value of some bilateral contributions made before 1967 (notably by the USA and the USSR) and of cash and vaccine pledged during the period 1967-1979 by India, the USSR and the Japan Shipbuilding Industry Foundation but received after 1979; these amounts have been omitted from Table 10.6.

An attempt was also made to place a cash value on the services of volunteer personnel. For accounting purposes, a figure of US\$750 per month was assigned, an estimate provided by one of the principal donor governments. This figure, as well as a number of other approximations that were made, undoubtedly understates to some degree the value of gifts in kind. All but impossible to estimate, and not included here, is the value of services provided by many local, non-governmental groups, such as the League of Red Cross and Red Crescent Societies; Kiwanis, Lions and Rotary Clubs; youth groups, such as the Boy Scouts and Girl Guides; and missionary groups. In a number of countries such groups were most helpful in organizing vaccination campaigns, mobilizing public support and, sometimes, performing vaccinations. A few contributed funds in support of local programmes, although in comparison with national and international contributions, the cash value of all such contributions was not large.

Although voluntary contributions were recognized by the Health Assembly to be an essential adjunct to the WHO regular budget, such support was difficult to obtain. Every year, Health Assembly resolutions requested

all countries to provide additional support and every year the Director-General sent letters to all Member States and to relevant international agencies, referring to the Health Assembly resolution and asking for help. Smallpox eradication programme staff regularly met potential donors at the World Health Assembly and during special visits to national capitals and embassies; special meetings of potential donors were convened; and influential national figures who were sympathetic to the programme were regularly contacted to seek their good offices in obtaining support. Despite these efforts and despite the fact that the eradication of smallpox would be of great benefit to all countries, contributions were modest at best. This may have reflected a certain scepticism as to the feasibility of eradication; however, it also reflected the fact that WHO, except for malaria eradication, had not previously been active in seeking supplementary contributions and governments were unaccustomed to making them. As Table 10.7 shows, except in respect of malaria eradication, the contributions to the special accounts that made up the Voluntary Fund for Health Promotion did not exceed US\$2 million in any year until 1968, and of all the contributions made between 1967 and 1975, 18% were for smallpox eradication.

Vaccine for the programme was obtained entirely from voluntary contributions or local production. From 1967 to 1979, 27 countries contributed 407 million doses of vaccine to the Voluntary Fund, more than 60% of this coming from the USSR. Although industrialized countries provided most of the donated vaccine, notable contributions of vaccine were also made by Argentina, Brazil, Colombia, Guinea, India, Iran, Kenya, Peru, Philippines and Thailand.

Efforts to obtain support from UNICEF and the United Nations Development Programme (UNDP) proved disappointing, although both agencies had previously given significant support to other WHO programmes, as well as some support for smallpox eradication before 1967. Between 1967 and 1972, UNICEF provided US\$427 878 for vaccine and vaccine production equipment but none thereafter—a policy reflecting its disappointment with the lack of progress in malaria eradication and its decision not to support another attempt to eradicate a disease. The possibility of support from UNDP was explored with the resident

representatives in several countries, but lack of interest, the complexities involved in developing suitable proposals and the delays in securing their approval restricted support to US\$299 344.

Between 1967 and 1970, over half of all international expenditure on smallpox eradication was met by bilateral contributions (Table 10.8), representing primarily United States support for the programme in western and central Africa and contributions of vaccine by the USSR to India and several smaller Asian countries. With the achievement of smallpox eradication in western and central Africa in 1970, support for that programme began to be phased out and India, during the early 1970s, began to rely increasingly on domestically produced vaccine. Bilateral contributions diminished proportionately, and after 1972 exceeded US\$1 000 000 only in 1974 and 1975.

Expenditure from the Special Account for Smallpox Eradication up to the end of 1973

was accounted for primarily by the distribution of donated vaccine. The amounts increased steadily over the years, reaching US\$845 150 in 1973. Two-thirds of the expenditure on smallpox eradication in 1973, however, were met by WHO's regular budget.

Contributions to the Voluntary Fund increased significantly from 1974 onwards. In the autumn of 1973, smallpox eradication activities had been intensified in Asia, but the problems encountered in India proved far more formidable than had been anticipated (see Chapter 15) and, in response to special appeals for assistance, Sweden began to contribute substantial sums to the Voluntary Fund for use in that country, amounting in total to more than US\$9 million during 1974-1976. As difficulties mounted in Bangladesh as well, Sweden, and later Norway and Denmark, joined together to provide more than US\$5 million for its programme. Substantial additional assistance for India was also provided by the Tata Iron and Steel Company of India, by Iran and by OXFAM.

In 1974, it was also possible to intensify the programme in Ethiopia, the only endemic country outside Asia, thanks to support from the United States Public Health Service, which began to make funds available for leasing helicopters, nearly US\$2 million being provided for this purpose from 1974 to 1977. AID contributed US\$3 million to the Voluntary Fund in 1976-1977 in support of the Ethiopian programme and additional assistance was provided by Australia, Austria, Finland, the Federal Republic of Germany and Japan. Finally, with the reintroduction of smallpox into Somalia in 1976 (see Chapter 22), special appeals for funds brought contributions from the USA and from UNDRP. Meanwhile, cash contributions which could be used wherever required were provided by Canada, the Netherlands, the United Kingdom, Switzerland and the Japan Shipbuilding Industry Foundation.

By 1977, the year in which the last endemic case occurred, the Voluntary Fund covered more than 70% of all expenditures; during the period of certification activities, 1978-1979, WHO regular budget allocations were sharply decreased and the coverage by the Voluntary Fund increased to 80-90%.

Although the increase in voluntary contributions from 1974 onwards coincided with a growing recognition of the feasibility of global smallpox eradication, the donations proved to be almost as difficult to obtain as in

earlier years. A review of the origin and history of each of the contributions shows that personal, often repeated, appeals by individual members of the smallpox eradication programme staff had to be made in order to obtain each contribution.

### SUPPLY OF VACCINE AND VACCINATION INSTRUMENTS

The availability at all times of satisfactory freeze-dried vaccine and vaccination instruments was essential to the successful execution of the programme. Without vaccine and bifurcated needles or jet injectors, programme staff could do nothing; with them, methods could usually be devised to deal, at least to some extent, with shortages of transport and equipment, and so sustain both momentum and morale. Because of the importance of vaccine and vaccination instruments, Chapter 11 is devoted exclusively to the subject. Here, we summarize the methods used to ensure that both were readily available to all endemic countries and to those adjacent to them.

#### Vaccine Requirements

It had originally, but erroneously, been assumed that the provision of adequate quantities of suitable freeze-dried vaccine would not present a major problem. It was believed that, for most endemic countries, if

sufficient vaccine were not already available, it would either be provided in the form of bilateral contributions or soon be produced in the endemic countries themselves. Additional requirements would be met through contributions made through the Voluntary Fund for Health Promotion, the pledged annual contribution of 25 million doses by the USSR being considered almost sufficient for this purpose.

From what was known in 1967, adequate supplies of vaccine appeared to be available. In the Americas a number of laboratories were already producing freeze-dried vaccine and an agreement was signed by the Pan American Health Organization with Connaught Laboratories of Canada to provide for continuing consultation, the training of technicians and the monitoring of vaccine throughout that region. It seemed, therefore, that this region was already self-sufficient, or soon would be. In the African Region, the programme in western and central Africa was being carried out with the assistance of the USA, which provided the necessary vaccine to 20 countries. In virtually all other countries, some type of vaccination programme was in progress and it was assumed that many had already obtained satisfactory vaccine from some source, although it was recognized that additional vaccine would be required if the programmes were to be intensified. In the South-East Asia Region, only Nepal and possibly Indonesia among the endemic countries appeared to require vaccine. India's needs were being met by domestic production and bilateral contributions from the USSR.

Table 10.8. International expenditure on smallpox eradication, 1967-1979 (US\$)

Year	WHO regular budget	Voluntary Fund for Health Promotion, Special Account for Smallpox Eradication	Other organs of United Nations system	Bilateral support	Total
1967	2 395 816	194 889	526 476	3 911 700	7 028 881

Afghanistan and Burma were also receiving vaccine from the USSR. In the Eastern Mediterranean Region, Pakistan was thought to be producing sufficient vaccine for its own needs in a laboratory in Dhaka, and the quantities required for Ethiopia, Somalia, the Sudan and Yemen were thought not to be great.

In 1967, a detailed survey of the amount and quality of vaccine being produced throughout the world revealed that the situation was much less satisfactory than had been thought. It was discovered that much of the vaccine then in use was produced by laboratories which did not test it for stability, while some laboratories determined potency simply by vaccinating a group of young children. When tested by the 2 WHO reference laboratories, much of the vaccine from developing countries and some from industrialized ones did not meet the international standards.

During the first 2-3 years of the Intensified Programme, the provision of vaccine was not a major problem, however, because of the time required for national programmes to organize activities aimed at increasing substantially the number of vaccinations performed. Of the countries in which major programmes began in 1967, Brazil produced sufficient vaccine for its own needs and, as has already been mentioned, the countries of western and central Africa were supplied by the USA. To ensure an adequate supply of vaccine of proven potency to meet the needs of other countries, a number of measures had to be taken quickly: (1) vaccine production laboratories in endemic countries were supported by the provision of consultants, equipment and production manuals; (2) the WHO reference laboratories agreed to test all batches of vaccine produced by newly established laboratories and to participate in research and other activities which would enhance and/or simplify production methods; (3) a system of international quality control was established for all vaccine used in the Intensified Programme, whether locally produced or donated through bilateral assistance or by WHO; (4) vaccination devices were tested and introduced which used less vaccine than conventional techniques; and (5) additional contributions of vaccine were sought. As a result, sufficient vaccine of adequate quality was eventually ensured for every endemic country, although for many years reserve supplies remained perilously low.

**Plate 10.24.** Ryoichi Sasakawa, President of the Japan Shipbuilding Industry Foundation, presents a cheque for US\$500 000 to F. J. Dy, Director of the WHO Regional Office for the Western Pacific in November 1975. Masami Tanaka, Minister of Public Health of Japan, stands between them. The Foundation later increased its support to WHO for smallpox eradication to a total of nearly US\$1.8 million, the largest amount given by a nongovernmental organization.

### Support for Production Laboratories in Endemic Countries

Of the commonly used vaccines, smallpox vaccine was the easiest to produce and laboratories already existed in a number of developing countries. Priority was given to the support of laboratories in the countries with the largest populations in order both to improve the quality of their vaccine and to increase their capacity, in the expectation that voluntary contributions would meet the needs of others. A first step was to simplify and standardize production methods. The principles on which vaccine production was based were similar throughout the world, but techniques differed widely from one laboratory to another. In 1968, therefore, a meeting of the most experienced vaccine producers was convened to develop a manual (SE/68.3 Rev.2) which described in detail the optimum production procedures. Selected consultants then repeatedly visited laboratories in the endemic countries to help them to improve methods and expand capacity. On the basis of their recommendations, additional equipment and supplies were provided. Vials of seed virus for use in production, as well as

reference specimens for testing, were prepared and distributed by the National Institute of Public Health, Bilthoven, Netherlands; when the laboratories began production, batches of vaccine were tested by one or the other of the two WHO reference laboratories.

Year by year, the quantity of vaccine produced in the developing countries increased and its quality improved. In the South-East Asia Region, Burma became self-sufficient in 1969 and Indonesia in 1970; India's 4 laboratories slowly but steadily increased the quantity and quality of their vaccine. The laboratory in Dhaka likewise increased production to provide sufficient vaccine for East Pakistan, although some additional supply had to be provided during the intensified programme in 1973-1975, in what was then Bangladesh. In the African Region, support was provided to laboratories in Guinea, Kenya and Nigeria in the hope that they might serve as producers for large regions of eastern and western Africa. Kenya, by late 1968, was able to produce sufficient vaccine for several countries in eastern Africa; the laboratory in Guinea took much longer to begin production and never succeeded in producing large quantities; the laboratory in Nigeria produced only a few satisfactory experimental batches. In the Americas, most of the countries conducting programmes quickly became self-sufficient and contributed vaccine to others requiring it. Brazil, as noted above, produced sufficient vaccine for its own needs and, although many batches did not meet international standards, especially for stability, the vaccine was effective provided that it was kept cold until the time of application. The Eastern Mediterranean Region was ultimately to require the largest amounts of vaccine. Efforts to establish a laboratory in Pakistan, the country with the largest population in the region, failed because of national administrative problems, but by 1973 sufficient vaccine to meet most of Pakistan's needs was being provided by Iran. Assistance was also given to laboratories in Ethiopia, Iraq and the Syrian Arab Republic, but none of these succeeded in producing more than small quantities of satisfactory freeze-dried vaccine.

By 1971, approximately 250 million doses of vaccine were being produced annually in the endemic regions, and by then all the vaccine used in national programmes, except in Brazil, met international standards.

### Vaccine Donations

Most of the contributed vaccine was provided under bilateral agreements by the USSR, which donated more than 1400 million doses from 1958 to 1979. The USA provided more than 190 million doses, primarily to the western and central African countries, also under bilateral agreements. Contributions from other countries usually amounted to no more than a few million doses each year (see Chapter 11, Table 11.15 for the quantities contributed to WHO between 1967 and 1984). In part, this was because most industrialized countries produced their own vaccines in small national or quasi-national laboratories. Most produced little or no freeze-dried vaccine, preferring instead the glycerolated liquid vaccine, which could be dispensed more conveniently in single-dose capillaries. Although the vaccine had to be kept constantly under refrigeration, this caused little difficulty for the industrialized countries.

Except for the vaccine provided under bilateral agreements by the USSR and the USA, virtually all vaccine contributions were made through the WHO Voluntary Fund for Health Promotion. Until 1967, arranging for the acceptance and shipment of vaccine contributed to WHO was complicated and time-consuming, usually requiring 6-18 months (see Chapters 9 and 11). Several measures were therefore taken to reduce the processing interval to only 6-8 weeks. The Smallpox Eradication unit assumed responsibility for arranging for tests of batches of vaccine proposed for donation and the National Institute of Public Health, Bilthoven, agreed to examine specimens as soon as received. Specimens were shipped promptly and the results reported by telex or telephone. One obstacle to rapid processing was the requirement that vaccine titres should be determined after incubation for 4 weeks at 37 °C. When it was shown in 1969 that all vaccine batches with an adequate titre after incubation for 1 hour at 100 °C also met conventional stability tests (Arita, 1973), it was possible further to reduce the time required for testing by 4 weeks. Another problem had been that of arranging for the prompt shipment of vaccine from donor laboratory to recipient country. Many donors waited until vaccine was requested before beginning production but, even when it was available in stock, many delays occurred in arranging for international shipment. WHO

[illegible]

<sup>a</sup> From 1968 onwards, bifurcated needles started to be used for vaccination, enabling 1 dose to be used for the vaccination of 4 people. Hence numbers of doses are not necessarily the same as numbers of vaccinations performed. In addition, wastage of vaccine in the field must be taken into account. It can safely be assumed that the number of doses should be multiplied by 2 to give the number of vaccinations. Supply of vaccine by WHO was discontinued after 1980 when the eradication of smallpox was confirmed by the World Health Assembly.

**Now part of the United Arab Emirates.**

therefore decided to request that all vaccine, after testing, should be shipped to Geneva for storage in refrigerated facilities leased by WHO. With this vaccine reserve, WHO administrative staff were able to send out vaccine within 48–72 hours of receiving a request.

During 1967–1979, more than 360 million doses of vaccine were distributed to some 70 countries or organizations (Table 10.9), both vaccine and bifurcated needles being made available to all developing countries that requested them whether or not they were conducting a special eradication programme. Between 1967 and 1969, 15–20 million doses were distributed annually, a figure which increased to 30–45 million doses during the period 1970–1975. Until 1973, however, the balance between demand and available contributions remained a precarious one (Fig. 10.3). Nevertheless, no programme was suspended for lack of vaccine although, in some countries and during some periods, vaccine reserves provided enough for only 1–2 weeks of continuing operations.

Success in ensuring an adequate supply of vaccine must be attributed, in part, to the use of the bifurcated needle from 1968 onwards. Most of the vaccine was supplied in containers which provided 0.20–0.25 ml, sufficient to vaccinate 20–25 persons by conventional scarification methods and 4–5 times

that number with the bifurcated needle. For purposes of record-keeping, however, each vial continued to be regarded as containing 20–25 doses. For technical reasons vaccine could not be packaged in vials containing smaller quantities than 0.20–0.25 ml; had it been possible to do so, wastage would have been reduced, since the prescribed practice was to discard any reconstituted vaccine that remained at the end of the day.

The vaccine supply depot in Geneva proved invaluable and most vaccine was dispatched from it. In the interests of economy, however, some donated vaccine was sent direct from the producer to recipient countries. When Kenya began to produce more vaccine than it required, stocks were shipped direct from its laboratory to neighbouring countries; Iran's contributions were shipped to Pakistan; South American countries sent vaccine to one another; and Indian bilateral contributions were shipped direct to Bangladesh; Nepal and Sri Lanka in 1975–1976. Several regional offices proposed that regional depots should be established, but the small reserves available made this impracticable. When, in 1976, vaccine reserves at last began to accumulate, a second depot was created in New Delhi at the Regional Office for South-East Asia. Unfortunately, mechanical problems with the refrigeration units and frequent interruptions in the electricity supply made it necessary to close this depot down, and the international reserve of vaccine was subsequently stored by WHO in two locations in Switzerland—Geneva and Lausanne.

Fig. 10.3. Donations of smallpox vaccine to WHO: numbers of doses received and distributed, by year, 1965–1979.

### Development of Vaccination Devices

New vaccination devices used less vaccine than, and eventually replaced, the traditional scarification instruments used before 1967. Smallpox vaccination with jet injectors, first tested in a pilot project in 1965, was rapid and required only one-third as much vaccine as conventional methods. Jet injectors were widely used in three of the initial major campaigns—in Brazil (see Chapter 12), in western and central Africa (see Chapter 17) and in Zaire (see Chapter 18). However, they were little used elsewhere, partly because of the difficulty of maintaining and repairing them but mainly because the simple, effective and cheap bifurcated needle became available

in 1968, only a year after the Intensified Programme began.

The historical development of the bifurcated needle is described in Chapter 11, in which the needle itself and the containers used for sterilizing needles before use are illustrated (see Plate 11.15). Introduced in 1968 for use with a multiple-puncture technique devised by Henderson and Arita, bifurcated needles had replaced traditional methods in most countries by the end of 1968 and were in use everywhere by 1970. They cost only US\$5 per 1000 and could be reused repeatedly after sterilization. Besides conserving vaccine, they were so simple to use that a local villager could be trained in only 10-15 minutes to reconstitute vaccine and to perform effective vaccinations.

### Vaccine Practices and Complications

The WHO Handbook recommended that, in endemic and neighbouring countries, everyone, including infants, should be vaccinated. The only recognized contraindication to vaccination related to "individuals who were obviously severely acutely ill" and whose death, if it occurred, might be mistakenly attributed to vaccination. This recommendation was based on the rationale that in endemic areas the risks of complications following vaccination were far lower than those associated with contracting variola major or even variola minor. Moreover, it was recognized that most vaccinations would be performed by vaccinators who would be unable to identify conditions commonly accepted as contraindications to vaccination in non-endemic countries, such as immunological disorders, neoplastic disorders affecting the reticuloendothelial system, and treatment with corticosteroids, antimetabolic drugs or other chemotherapy.

The WHO Handbook described several possible vaccination techniques: multiple-pressure or scratch using a needle or rotary lancet, and the jet injector. An important change from conventional vaccination practice at the time was the recommendation that "the best skin preparation is none at all", and that "if the site is obviously caked with dirt, a cloth moistened with water may be used to wipe the site". This recommendation was based on a number of studies which had demonstrated that conventional methods for cleansing the skin with acetone or alcohol had

little effect in reducing the number of bacteria but could destroy or partially destroy vaccinia virus if the vaccine was applied before the liquid had dried.

During the programme, few serious complications were observed which could be attributed to vaccination. The usual response to vaccination—a pustule, with sometimes a sore arm and fever—was readily tolerated although it caused some people to refuse vaccination—for example, agricultural workers during the harvest period. Disseminated vaccinia was observed in only a few patients. Cases of post-vaccinal encephalitis, a far more serious complication, undoubtedly occurred but because of the large number of prevalent illnesses which caused cerebral symptoms (e.g., malaria), it was difficult to know whether cases of encephalitis-like illness were complications of vaccination or were due to other causes. An unusual group of complications occurred in Ethiopia among nomads of the northern Ogaden desert, a number of whom, following primary vaccination, developed a deep, non-pustular craterous lesion at the vaccination site which penetrated as deep as the muscle fascia. All those affected reported that they had applied the ashes of a thorny shrub to the lesion. Efforts to interest pharmacologists in this phenomenon were unsuccessful but the problem ceased when a sulfa powder was distributed and the nomads were advised to use this instead of the ashes.

### SURVEILLANCE AND NOTIFICATION OF SMALLPOX CASES

Whereas, up to 1967, smallpox eradication programmes consisted entirely of mass vaccination campaigns, from 1967 onwards they also included surveillance. Little attention had been given to surveillance and the notification of smallpox cases either internationally or within countries up to that time; in the endemic countries, there were no nationally organized programmes designed to investigate and contain reported outbreaks. From 1967, however, the indicator used for measuring the progress of the programme ceased to be the total number of vaccinations and was replaced by the numbers of reported cases of smallpox and of endemic countries. Epidemiological analysis of the cases provided important information from the point

of view of the strategy and tactics to be employed and the allocation of resources.

The difficulty of explaining the concept of surveillance to programme staff and of gaining their acceptance of it was not appreciated, however, when the programme began. Mass vaccination campaigns were familiar and well understood but because they were complex to organize and execute, little time and few resources were usually available for surveillance. Incorporating into programmes what had seemed to be a simple, basic concept required much of the time and energy of the senior WHO smallpox eradication programme staff.

### The Concept of Surveillance

The concept of a nationally supervised programme for reporting and investigating smallpox cases and containing outbreaks had, as its antecedent, the disease surveillance programmes of CDC in the USA (Langmuir, 1963). Dr Alexander Langmuir, its chief epidemiologist, had fostered the concept of surveillance since his appointment in 1949. He attributed the genesis of the concept to William Farr, who had been the superintendent of the Statistical Department of the Registrar General's Office of England and Wales in the 19th century. Farr's epidemiological analysis of cases and deaths over many years and by age group, area and season, made it possible to formulate hypotheses as to the way in which diseases were spread, which in turn suggested possible control measures and enabled forecasts of future trends in disease incidence to be made.

Dr Langmuir defined surveillance as the "continued watchfulness over the distribution and trends of incidence through systematic collection, consolidation and evaluation of morbidity and mortality reports and other relevant data". He pointed out that "intrinsic in the concept is the regular dissemination of the basic data and interpretations to all who have contributed and to all others who need to know". In developing surveillance in the USA, he focused primarily on diseases for which control measures were available, beginning with malaria, sylvatic plague and leprosy, and subsequently extended it to include diphtheria, poliomyelitis and other diseases. Working with state and local health officials, he and his staff obtained detailed information about reported cases, including

confirmation of the diagnosis by laboratory study and basic data regarding age, sex, race and place of residence and, depending on the disease, information regarding vaccination status, possible place of exposure, etc. These data were regularly analysed, appropriate control measures recommended and surveillance reports prepared and widely distributed.

Henderson had worked with Dr Langmuir since 1955 and had served from 1961 to 1965 as chief of the Surveillance Section at CDC. It seemed to him only logical to endeavour to apply the principles of surveillance to the eradication of smallpox. This was stated in the Director-General's report to the Nineteenth World Health Assembly (World Health Organization, 1966b; see Chapter 9), which Henderson, as a consultant to WHO, had helped to prepare. This approach was strongly supported by Dr Raška, Director of the Division of Communicable Diseases, who had been a keen proponent of epidemiological surveillance while working in his own country, Czechoslovakia (Raška, 1964).

The concept of surveillance as applied to the smallpox programme was succinctly described in the WHO Handbook as follows:

"The primary objective of the smallpox programme is the eradication of this disease. Surveillance is thus an essential component of the programme since the term 'eradication' implies that the number of indigenous cases of smallpox reach '0'... Surveillance represents a great deal more than case reporting alone. It is composed of several components:

- (a) The routine, systematic collection of data, amplified appropriately by special field investigations and studies
- (b) The concurrent analysis and interpretation of reported data and studies
- (c) The initiation of appropriate definitive action including field investigation, epidemic control, modification of operational campaign procedures, recommendations regarding vaccination, etc.
- (d) Widespread dissemination of the compiled and interpreted data to principal reporting sources and to others concerned with disease control activities."

### The Routine Systematic Collection of Data

A reporting network which provided for the collection of epidemiological data regarding each case of smallpox was the foundation of the system. Its goal was to ensure that each week all known cases of smallpox would be

reported by the peripheral health units in each country, through intermediate administrative units, such as districts and provinces, to national and, ultimately, to international authorities. The concept was simple, but there were formidable problems at every level in perfecting such a system.

Although this section deals primarily with surveillance at the international level, certain features and problems of national data collection systems need to be described in order to appreciate the quality of the data being provided in 1967 to WHO by national authorities in the endemic countries.

Reported cases of smallpox, which would be routinely notified if the system were functioning properly, inevitably represented only a portion of all the cases which actually occurred. The basic network of reporting units—health clinics, hospitals and dispensaries—documented only those who presented themselves for treatment. Many patients had no access to health care or did not go to health care units for fear of unwanted forcible isolation in a hospital or because they knew that there was no effective treatment. They could be discovered through searches or by field investigations of known outbreaks, but few health services undertook such activities. Even where there was complete notification of all cases seen by health units, the data provided only an indication of trends in incidence and of the geographical dispersion of the disease.

In all endemic countries, the notification networks themselves were seriously deficient. Usually, health units were supposed to provide weekly or monthly summaries of the number of patients seen, but smallpox was often only one of 25-50 different diseases that they were expected to report. Poorly supervised, overworked health staff customarily devoted little time to the preparation of lengthy reports which rarely led to any action being taken. Some regularly submitted reports to higher authorities but many did so only occasionally. In intermediate administrative units—such as states or provinces—and at national level, data were usually received and tabulated, often after extended delays, by clerical personnel whose responsibility was limited to ensuring that the data were entered accurately. Little notice was taken of whether all units reported or when they did so, and because the data were rarely used in programme operations, there was little incentive to improve the system.

All countries were expected to send to WHO weekly reports of cases of the so-called quarantinable diseases (smallpox, cholera, plague, yellow fever and typhus), and to indicate the areas in which they had occurred. Such routine reporting had been the practice since the adoption of the International Sanitary Convention of 1926, when receipt and publication of the information was the responsibility of the Health Organisation of the League of Nations, a function assumed by WHO on its foundation.

In WHO, in 1967, the receipt and tabulation of data on the quarantinable diseases was the responsibility of the International Quarantine unit, which later became the Epidemiological Surveillance and Quarantine Unit and in 1971 was renamed the unit for the Epidemiological Surveillance of Communicable Diseases; for convenience, it is referred to below simply as the "WHO quarantine unit". Reports were received direct from the countries concerned rather than through the WHO regional offices, and indicated the number of reported cases in each administrative unit, or "local area" as it was called, such as a district or county. The reports also specified which of the local areas were newly infected and which could be declared free of the disease. Each week a lengthy list of the existing and newly infected local areas in each country was published in the *Weekly epidemiological record* for each of the quarantinable diseases. In theory, this enabled quarantine officers and others concerned to determine whether or not a traveller had been in an area in which one of the diseases was present and to take appropriate measures. In practice, most health authorities recognized that reporting everywhere was deficient and usually considered the whole of a country to be infected if infection was present in any of its local areas.

The WHO quarantine unit also tabulated the number of cases reported. The data so compiled were considered to be the provisional official totals of cases, pending later receipt of annual reports from national governments. Such annual reports, when compiled and published some 3-4 years later by the WHO Division of Health Statistics, constituted the final authoritative international record of disease incidence. No attempt was made to reconcile the data in the provisional reports with those in the annual reports, and national authorities were seldom questioned as to the accuracy of the information provided.

### Changes in the International Data Collection System

The inadequacy of the routine data collection system for smallpox cases had been recognized in 1967 but not until much later did it become apparent just how inadequate it was. Smallpox eradication programme staff had assumed that, because smallpox was one of the principal diseases subject to international quarantine agreements and because most infected countries submitted weekly reports, albeit after long delays, it was one of the better-reported diseases. However, field investigations soon showed that not more than 1 case in 20 was being notified. Later, through facial pockmark surveys, it became apparent that probably not more than 1 case in 100 was being reported and, in some countries, such as Ethiopia, perhaps 1 in 1000. Despite the incompleteness of reporting, however, the notified data proved to be important from the beginning of the programme for decisions about priorities and resource allocations and for assessing progress; ultimately, they were essential in determining that transmission had been interrupted and in certifying that eradication had been achieved.

Efforts to improve the system began with the initiation of the Intensified Programme. Deficiencies became apparent almost immediately when WHO staff attached to national smallpox eradication programmes cited national data which differed from those reported to the WHO quarantine unit. When efforts were made to reconcile the two sets of figures, it was discovered that, in many ministries of health, there were two sets of data, one compiled by a statistical unit and one by smallpox eradication programme staff. The statistical unit's data were taken from routine reports submitted by states and provinces, while those of the smallpox eradication programme office were often revised to take into account additional cases discovered during field investigations, reports obtained by the staff from states or provinces which had failed to file reports with the statistical office, and information on reported cases which had been mistakenly diagnosed. It was usually of no importance to national eradication programme staff whether the statistical unit's data differed from theirs or not, since such differences had no bearing on their operations.

Through correspondence with the countries and discussions with the WHO quaran-

tine unit, WHO smallpox eradication staff sought to obtain the most complete national data available. In some instances, it was possible to obtain revised national figures extending over many months or several years, which usually showed much larger numbers of cases than those reported by the national statistical unit. The WHO quarantine unit did not take cognizance of such information because its responsibility was to compile only the current data officially reported to WHO and to maintain the registry of local infected areas. For the first three years of the Intensified Programme, two sets of data were maintained at WHO on smallpox incidence during the current and immediately preceding years. Depending on the WHO publication, sometimes one and sometimes the other set of data was used, but smallpox surveillance reports always used Smallpox Eradication unit data. In 1969, it was agreed that the Smallpox Eradication unit would assume the responsibility for all current data on smallpox cases and infected local areas, a procedure which reduced confusion and conserved manpower.

Meanwhile, through personal contact, correspondence and the publication of summaries of the smallpox situation in the *Weekly epidemiological record*, governments were urged to report more promptly and gradually began to do so. However, even as late as May 1970, reports from 5 countries were more than 4 weeks overdue and not until 1972 were reports received promptly from all the states of India (see Chapter 15). By the end of 1972, however, few reports from countries were delayed by as much as 2 weeks.

In 1970, another question arose in WHO Headquarters regarding what should constitute the authoritative international record of smallpox incidence. In that year, staff in the Division of Health Statistics observed that the numbers of smallpox cases in governments' annual summaries of disease incidence (a third data set) did not always agree with the data compiled by the Smallpox Eradication unit. Upon investigation, it was found that the differences usually reflected the fact that two sets of data had been compiled nationally. In other instances, clerical errors had been made in the annual summaries submitted, sometimes resulting, for example, in smallpox cases being reported by countries remote from endemic areas and with no known importations. These errors were quickly corrected by the governments concerned when they were

brought to their attention but such data had been accepted without question in previous years. Towards the end of 1970, it was decided that the data compiled by the Smallpox Eradication unit, based on what it considered to be the most accurate national data, should be used in WHO publications. Thus, what had once been three different sets of smallpox data in WHO became one.

The possible suppression of reports of smallpox cases by national authorities was a continuing concern, although it did not happen often. Such suppression was most marked in western Asian countries and resulted, in part, from the adverse consequences of reporting cholera cases during a recent pandemic. These reports had induced other governments to impose unwarranted barriers to trade and travel which had caused serious economic losses. Some feared that reports of smallpox might result in similar measures being taken and therefore suppressed them. Cases of smallpox, especially when they were numerous, were not easy to conceal, however, and WHO learnt about them from many sources, including embassies, travellers and persons working in international organizations. All rumours of outbreaks were followed up by WHO by telex and by correspondence and sometimes by personal visits. Even when it was certain that smallpox was present, publication of the information without official government approval was diplomatically impossible. The suppression of reports had 2 adverse consequences: it jeopardized the credibility of the programme and the eventual acceptance of global eradication; and it made it difficult for the countries concerned to mobilize health resources and community support in order to control the outbreaks. Although most health authorities eventually cooperated in reporting, 4 did not acknowledge the existence of cases until many months or years later, and 3 eventually experienced major epidemics. These are discussed in Chapter 22

(Somalia) and Chapter 23 (Iran, Iraq and the Syrian Arab Republic).

Throughout the programme, national totals of smallpox cases were corrected whenever better information became available so as to reflect more accurately the actual incidence. Data for 1967-1977 were most carefully scrutinized, but changes were also made in data for a number of years preceding 1967. For example, the data presented in this book show global totals for smallpox cases between 1959 and 1966 substantially greater than those in the report (prepared in April 1967) submitted by the Director-General to the Twentieth World Health Assembly. The totals for the years 1959-1962 are 6-20% greater and those for 1963-1966 are 34-74% greater (Table 10.10). The larger discrepancies after 1963 reflect the fact that smallpox eradication staff in most countries reviewed and revised national and state or provincial data only from 1963 or 1964 onwards.

### International Surveillance Reports

A basic precept of surveillance is, as has already been quoted from the WHO Handbook, the "widespread dissemination of the compiled and interpreted data to principal reporting sources and to others concerned with disease control activities". Accordingly, the first of what were intended to be quarterly international surveillance reports was issued by the Smallpox Eradication unit as a mimeographed document in September 1967. It was sent to some 200 persons, principally WHO staff concerned with smallpox eradication and national programme directors. A second report was issued in December 1967 and a third prepared in March 1968. Distribution of the third report was stopped, however, by senior WHO management staff, who believed that there were too many WHO reports and therefore decided to suspend most of them pending a

full review of WHO's publication policies. Eventually, it was decided that smallpox surveillance reports should be discontinued.

The coordination of a global programme was difficult enough, but without some mechanism for disseminating information on its status and the progress being made, the task appeared impossible. The matter was discussed in WHO in a series of difficult meetings extending over 8 weeks, and it was finally decided that a brief report on smallpox could be inserted periodically into the *Weekly epidemiological record*. From May 1968 onwards, such reports were published every 2-3 weeks.

Use of the *Weekly epidemiological record* had both advantages and disadvantages. The main advantage was that it was a well-established periodical with a circulation of some 5000 copies which reached a far larger audience than was possible with the mimeographed report. The disadvantage was that it published only epidemiological data, to the exclusion of other information which the smallpox eradication programme needed to have disseminated, such as the results of tests on the bifurcated needle and techniques for its use, and reports of the deliberations of relevant expert committees and scientific groups. Moreover, the periodical was normally sent by surface mail and not all WHO and national smallpox eradication programme staff had access to it. To solve these problems, it was agreed that additional copies of the smallpox surveillance section of the *Weekly epidemiological record* would be printed and sent by air mail, together with other special reports dealing with smallpox, to the 150-200 persons concerned with the programme. Thus began the practice of a special mailing every 2-3 weeks to all WHO and senior national smallpox eradication programme staff, a practice which ensured more rapid delivery than the traditional channels of communication through the regional offices. The WHO/SE, SE and SME series of documents listed with the references at the end of this book constituted most of the papers so distributed. Accounts by field staff were seldom prepared without considerable persuasion because, for many, English was not their mother tongue and few were experienced in writing papers for publication. A promise that smallpox eradication programme staff would edit all suitable papers increased the number submitted. Although the editorial burden was staggering, the papers proved invaluable in docu-

menting useful observations made in the course of the programme and in fostering evolutionary change.

Following the incorporation of the smallpox surveillance reports into the *Weekly epidemiological record*, its editor, Dr Ian Carter, began to transform the publication itself. Once unkindly referred to as "the laundry list of infected local areas", the periodical gradually became a substantive document dealing with many diseases and reaching an increasingly wider public. With time, the smallpox surveillance reports gradually increased in length and frequently appeared on the first page, but the prominence given to smallpox eradication troubled the responsible Assistant Director-General, who felt that other important disease problems were not receiving sufficient attention. He therefore directed that the smallpox reports should be relegated more often to the inside pages. Thereafter, by tacit agreement, the smallpox surveillance report appeared on the front page of the *Weekly epidemiological record* only twice a year, when the semi-annual summaries were published.

## RESEARCH

In 1967, few administrators or scientists believed that additional research was needed or would contribute to the achievement of smallpox eradication. This was understandable. A smallpox vaccine had been available and in use for more than 150 years and the commercial production of a thermostable vaccine had been perfected. The epidemiology of the disease under many different circumstances and in many countries had been described and the feasibility of eradication had been demonstrated in a number of developing countries. The basic task, as most saw it, was administrative—primarily that of organizing programmes to deliver vaccine to the population of the endemic countries. The attitude towards research was similar to that which had prevailed when global malaria eradication began in 1955. In that programme, research had been largely abandoned until 10 years later, when, with the programme progressing poorly, it was recognized that additional tools and different strategies were required. By then, however, competent and experienced research staff had turned to other fields. It was an important

lesson, and one which those in the Smallpox Eradication unit believed should be heeded.

In 1967, little smallpox research was in progress, and only US\$20 000 were allocated in the WHO budget for the support of such research. With so few resources and with only 4 medical officers in the Smallpox Eradication unit in Geneva, WHO could not undertake a comprehensive, well-organized research programme. However, it was hoped that field staff might be able to make significant contributions and, to stimulate their interest, some 20 areas requiring research were identified in the WHO Handbook. In consequence, many field staff undertook and participated in a wide range of important studies from the beginning of the programme.

One research area was of paramount importance—to establish with certainty whether there was any natural reservoir of variola virus. Since yellow fever eradication had been thwarted by the unexpected discovery of an animal reservoir, and in the light of the suggestions then being made that there might be a simian reservoir of malaria, the question naturally arose whether there might also be an unrecognized natural reservoir of smallpox. This question was dealt with in a series of planned studies involving many different investigators and laboratories.

Substantial amounts were eventually spent in support of research by many laboratories and, although no quantitative data are available, they were far greater than the sums provided by WHO. Of especial note are the contributions of CDC in Atlanta, the Moscow Research Institute for Viral Preparations, the National Institute of Health in Japan, the Department of Virology of St Mary's Hospital Medical School in London, the National Institute of Public Health in the Netherlands, Wyeth Laboratories in the USA, the Calcutta Institute of Tropical Medicine in India, the Public Health Institute in Bangladesh, the Pakistan Medical Research Centre in Lahore and the University of Maryland School of Medicine in Baltimore, whose scientists worked in Pakistan.

In retrospect, it is unlikely that the global eradication of smallpox would have been achieved without the broader understanding of smallpox, its virology and epidemiology, which the research conducted after 1967 provided. The results of such research include: the redefinition of the epidemiology of

smallpox and because of this, a change in the strategy so as to place increased emphasis on surveillance and containment; an improved understanding of the efficacy and duration of vaccinal immunity and, as a result, changes in practices pertaining to revaccination; a great improvement in vaccine production and testing procedures; the development of a new technique of vaccination, employing a new instrument; the genetic mapping of variola and vaccinia viruses to provide new insights into the relationships of the orthopoxviruses; the discovery and characterization of human monkeypox; and the development of sample survey techniques.

The research programmes and the observations made are described in detail in the appropriate chapters of this book. For this reason, only the highlights of some of them are described here so as to place them in the context of the development of the global programme.

### A Natural Reservoir of Smallpox

From 1967 onwards, attention was focused on determining whether smallpox virus could persist in nature outside the human being. If smallpox were found to persist in an enzootic state, or if there were a closely related animal orthopoxvirus which could infect humans and whose transmission could be sustained in man, it was unlikely that smallpox could be eradicated. No less important was the question of how long variola virus could persist in nature, since this, too, had implications for the possible recurrence and re-establishment of infection in areas in which transmission had been interrupted. These problems are discussed in Chapters 2, 29 and 30.

The first review of the available data dealing with a possible animal reservoir of variola virus was published by Arita & Henderson (1968). They reasoned that, if there were a natural reservoir of variola virus, non-human primates were important candidates. As is discussed in the paper, a few reports had suggested that smallpox outbreaks did occur naturally in primates, but most of them dated from the 19th century. In view of the extent of endemic smallpox in countries in which primates were found and the paucity of reports of possible outbreaks in the present century, it seemed unlikely that primates really were a reservoir, but confirmation was

required. Also of interest was the closely related monkeypox virus, first described by Magnus et al. (1959) after an outbreak among a colony of laboratory primates and subsequently reported in 3 other laboratories. No human infection had occurred, but because adults in close contact with the animals were few and probably well vaccinated, no conclusions could be drawn about the possible infectivity of the virus for man. To study the matter further, Arita, in 1967, conducted a survey of 26 biological institutions which handled large numbers of primates to ascertain whether other, unpublished, outbreaks had occurred, to discover the circumstances associated with such outbreaks and to find out whether there had also been human infections. Five other outbreaks among primates came to light but no human cases. Almost all the illnesses occurred in Asian species and were clinically similar to those observed when primates were experimentally infected with smallpox.

To consider the problem of monkeypox and to develop a research agenda, a meeting of investigators from 6 laboratories (the Informal Group on Monkeypox and Related Viruses) was convened by WHO in March 1969 in Moscow. Thereafter, the investigators met every 2 years to plan a wide range of studies on the experimental infections of primates and other mammals with variola and monkeypox viruses and serological surveys of primates in Africa and Malaysia. New impetus to the efforts was given by the discovery of the first human monkeypox cases in 1970, and the working group was expanded to include epidemiologists and mammalogists. Subsequently, special field surveys were initiated to define the problem; these continued up to 1986 (see Chapter 29). They provided important substantiating evidence that no mammalian reservoir of smallpox existed and that monkeypox, confined to villagers in the tropical rain forest, could not be maintained by person-to-person transmission.

A second problem was to determine whether variola virus could persist in nature on fomites such as cloth or as scabs, and cause infection in man many months or even years later. That this was a cause for concern had been suggested in studies by investigators in the Netherlands, who demonstrated the survival of variola virus in scabs for as long as 13 years (Wolff & Croon, 1968). Whether the virus was of sufficiently high titre or in a

form such that man could be infected was unknown. The possible persistence of variola virus in nature was also suggested by anecdotal accounts, dating from previous centuries, of cases and outbreaks following the exhumation of the body of a person who had died of smallpox and of cases said to have occurred in newly reoccupied houses in which a smallpox patient had died months or years before. The validity of these observations was uncertain because all had been reported from areas in which smallpox was then widely endemic. Also of concern were variolators in Africa and Asia, who were known to collect and retain scabs and pustular material for periods of a year or more.

To determine the possible risk of the persistence of viable variola virus under field conditions required many different epidemiological and laboratory studies. Laboratories in Bangladesh and India undertook to determine the duration of the viability of variola virus under different conditions of temperature and humidity. Epidemiologists were instructed to document with care the source of infection of cases, especially those in which there was a possibility of exposure to virus which had persisted in the environment. Special efforts were made to determine the source of infection of outbreaks in all countries thought to be free of smallpox. Variolators were contacted and questioned in detail about their experiences in retaining smallpox material, and variolation material was obtained from them for titration in the laboratory. The results of these studies are described in Chapters 2 and 30. Ultimately, it became clear that, even under favourable conditions of low temperature and humidity, the virus did not survive for more than a few days or weeks in a form which could induce infection, unless inoculated, as in variolation. Even in this case, variolators reported that they had difficulty in inducing infection with material retained for longer than a year.

### Epidemiological Observations

Of the many epidemiological observations, the most important were those which indicated that surveillance and containment should be accorded a much higher priority than had initially been appreciated. The first and most comprehensive of the field studies were those conducted in Pakistan and Bangladesh (then East Pakistan) during 1965-1968

and directed by scientists from the University of Maryland, USA, and the Pakistan Medical Research Council (see Chapters 4 and 14). In careful studies of the characteristics of the spread of smallpox, they showed that, even in highly infected areas, cases tended to occur in clusters rather than being widely disseminated, and that the disease spread less rapidly and less easily than was commonly believed and only through close personal contact. Moreover, during periods of seasonally low transmission, they found few continuing chains of smallpox transmission, mainly in urban areas. These characteristics suggested that the spread of smallpox could be more rapidly interrupted if greater emphasis were placed on the discovery of cases and the containment of outbreaks, especially during the season when transmission was at a low level and in urban areas. Observations in eastern Nigeria in 1967, in India in 1968, and in Brazil and Indonesia in 1969 confirmed the practicability of this approach. These observations were made known to all smallpox eradication programme field staff, but the basic concepts of surveillance and containment were slow to be accepted, having to be rediscovered and/or demonstrated in special programmes in most areas before they were incorporated into programmes.

Many other studies and observations arising from field programmes led to changes in strategy and operations (see Chapters 4 and 12-22). Among these were studies which showed that variola minor could persist for long periods among small nomadic groups, necessitating special surveillance procedures; that women in Afghanistan, confined to their houses by the practice of *purdah*, were mostly immune owing to a previous attack of the disease or to vaccination and that special vaccination programmes for them were unnecessary; and that the airborne transmission of variola virus over a distance was possible but only under exceptional circumstances and within buildings and so was not of concern. Methods were developed by which to estimate the incidence of smallpox in previous years, and special studies documented the frequency of persistence of facial pockmarks, observations which were important in deciding on the strategy for certification.

Few investigations were undertaken which required substantial laboratory support, partly because many of the studies required no more than physical observations of lesions or scars, and partly because few laboratories were

equipped to process large numbers of specimens. Studies which did involve laboratory support were conducted in Bangladesh, India, Somalia and Zaire and concerned the behaviour of other animal poxviruses (see Chapter 29) and the pharyngeal excretion of variola virus among contacts of patients (see Chapter 4).

### Vaccination Practices

Through research, not only did better vaccination instruments come into universal use but other vaccination practices also changed. Policies with regard to the youngest age for vaccination and the recommended frequency of revaccinations were changed. In most endemic countries, in 1967, primary vaccination was not given until the child had reached 3-12 months of age, and revaccination was performed every 3-5 years. The vaccination of neonates, however, had long been known to be a safe and effective practice and, in fact, had become a standard procedure in some countries of eastern Asia (Urner, 1927; Moodie & Cheng, 1962). Dr A. R. Rao's confirmation of these observations, in a WHO-supported programme in southern India, served to encourage wider acceptance of the practice, which made it easier to achieve higher levels of vaccination coverage during mass vaccination campaigns and enabled very young children to be protected during outbreak containment. That immunity following vaccination might be far more long-lasting than had been thought was suggested by field observations which showed that, even in well-vaccinated populations, 80-95% of cases occurred among those who had never been vaccinated. More precise measurements of vaccine efficacy subsequently confirmed that high levels of immunity continued for at least 10-20 years. These findings, documented early in the programme, led to a shift in the emphasis of vaccination campaigns from an effort to reach the entire population to approaches which would ensure that everyone had received primary vaccination at some time.

### Vaccine Production and Testing

In 1967, much was known about commercial methods for the production of freeze-dried smallpox vaccine and a production manual

was issued by WHO in 1968 (SE/68.3 Rev.2). Nevertheless, several studies were undertaken to examine certain aspects of the process, such as the optimum day for harvest to ensure maximum virus yield, the yields of virus produced by different strains, and alternative methods of purifying the vaccine and reducing bacterial content (see Chapter 11). Testing procedures were thought to have been standardized, but when different laboratories obtained quite different results on testing the same batches of vaccine, studies showed that slight but previously acceptable variations in technique were responsible; these were corrected. Although collaboration among potentially competing production laboratories is uncommon, this was not the case in the smallpox eradication programme. Laboratories in Canada, Czechoslovakia, the Netherlands, the USSR and the USA cooperated and shared information in solving problems, and their findings were communicated to all production laboratories.

### Characterization of the Orthopoxviruses

An examination of the similarities and differences between variola virus and other orthopoxviruses was important in assessing the likelihood that such a virus might, in some manner, mutate to a form whose virulence and transmissibility were such that infection could be sustained in man. Support for studies aimed at a more precise characterization of orthopoxviruses was provided by WHO to laboratories in London and Birmingham (England), Atlanta (USA), Tokyo (Japan) and Moscow (USSR), each of which committed substantial additional resources of its own. The importance of these studies increased with the discovery, in the early 1970s, in the Netherlands and in the USSR, of virus strains apparently isolated from animals and having characteristics indistinguishable from those of variola virus. Until the discovery of restriction endonucleases, which enabled the DNA structure of viral strains to be analysed, these analyses relied on biological markers, such as growth properties in different animals and cells and the optimum temperature for growth. The techniques were complex and time-consuming and the interpretation of the results was often uncertain. Ultimately, restriction endonuclease analyses of viral DNA proved of the greatest value. The isolates of variola-like viruses obtained

from animals in the Netherlands and the USSR were eventually shown to have been laboratory contaminants (see Chapter 29) and genetic analysis showed that it was highly unlikely that any of the large number of animal orthopoxviruses could be transformed by one or even several mutational steps into a virus which resembled variola virus.

### Summary

Even from this brief recapitulation, it is apparent that the epidemiological and laboratory research stimulated and coordinated by WHO contributed materially to the achievement of smallpox eradication. The effort was not, overall, a wholly integrated and comprehensively planned effort and was only modestly supported by WHO funds, but it was remarkably well directed towards finding solutions to operational questions and needs. Of signal importance was the ready cooperation of the investigators and their willingness to make available their papers and their data before publication. This, in turn, permitted the earliest possible application of new findings.

## STRATEGIES AND TACTICS IN THE EXECUTION OF NATIONAL PROGRAMMES

### Introduction

A survey of the approaches adopted in national vaccination campaigns and in surveillance and containment measures is provided in this section as an introduction to Chapters 12-22, which describe field operations in the various countries. The principles and practices were common to most but many aspects of the structure and method of operation of each national programme were unique, since each had to be adapted to the prevailing administrative, social, demographic and geographical conditions and each changed with time in response to experience and needs.

As has previously been described, the basic strategy for national programmes called for 2 different activities: (1) mass vaccination campaigns, assessed for both coverage and take rates by special teams; and (2) surveillance and containment of outbreaks. As infor-

mation accumulated on the extent of vaccinal immunity and the epidemiology of smallpox in the different countries, it became apparent that mass vaccination campaigns, particularly in Asia, were less important than the discovery and containment of outbreaks. Vaccinal immunity was found to be generally higher in most countries than had been expected and, in some countries, smallpox cases were so few that a comparatively simple surveillance and containment programme could serve to interrupt transmission.

Because mass vaccination campaigns were the traditional control method and were most readily accepted by national authorities, all endemic countries and many of those adjacent to them conducted such campaigns. While perhaps unnecessary in some areas, they served an important additional function in that vaccination teams, moving from village to village, were able to detect unreported cases of smallpox or to confirm its absence.

Surveillance-containment programmes, however, were frequently slow to begin, because the logistics of mass vaccination campaigns were so demanding and the techniques unfamiliar. Some programmes, adopting the tactics used for malaria eradication, deliberately delayed the commencement of surveillance until mass vaccination had been completed, an activity which they equated with the "attack phase" of the malaria programme. It was not always easy to persuade national programme staff and WHO smallpox eradication advisers that surveillance-containment operations should begin immediately and be accorded as high a priority as mass vaccination.

The importance of surveillance and containment was emphasized in discussions at the World Health Assembly and by Health Assembly resolutions in 1968 and 1969, and again by an explicit resolution of the Executive Board (EB45.R20), subsequently endorsed by the Twenty-third World Health Assembly (1970), in which the Board requested "all countries to take appropriate steps to improve further case-reporting and to adopt as an objective the immediate investigation and containment of all reported cases and outbreaks of smallpox from 1970 onwards" (World Health Organization, 1973a). Much effort was devoted to accomplishing this objective and demonstration-type programmes were organized to encourage it. Its importance was further reinforced

in numerous publications and communications. From 1969 onwards, smallpox eradication staff at WHO Headquarters recommended that surveillance-containment measures should be given priority over mass vaccination but because change was slow to come, they proposed in 1972 that all resources should be directed to surveillance-containment and that mass vaccination should be stopped. Although this proposal did not reduce the interest in mass vaccination on the part of most national authorities, it ultimately served to focus sufficient attention on surveillance and containment to permit the development of satisfactory programmes. To suggest that mass vaccination was unnecessary in any circumstances was recognized to be extreme and simplistic but it seemed necessary to do so at the time in order to alter national strategies. This was not without certain repercussions, however. By the time the emergency programme was introduced in Somalia in 1977, the principle of surveillance-containment had acquired a doctrinal quality and some WHO smallpox eradication advisers argued that it was heretical to conduct mass vaccination campaigns in any area, whatever the need (see Chapter 22).

The most important factors determining the success of all programmes were the quality of senior staff at the national level and their willingness to go into the field to see for themselves what progress was being made, to find solutions to problems and, by their example, to encourage lower-level supervisors to do likewise. In most countries, it was both traditional and accepted for supervisors, even at the lowest administrative levels, to remain in their offices. Many considered it demeaning to leave them, and those who wished to do so frequently lacked the necessary authority or transport. Supervision was customarily provided through verbal orders and written directives, and the results of programmes were assessed, if at all, through written reports, often of dubious veracity. In the smallpox eradication programmes, the supervisors were provided with transport, and WHO staff and consultants, by their example, played an important role in helping to change traditional patterns. Frequently, it was found that national and WHO smallpox eradication programme supervisors were almost the only supervisory staff to visit health programmes in the field or district centres and dispensaries. This type of frequent contact between supervisors and field personnel not only served to

resolve problems more rapidly and to redirect activities more efficiently but also proved invaluable in sustaining morale and interest.

In the following pages, the general practices followed in mass vaccination campaigns are discussed first, followed by those in the surveillance-containment programmes.

### Mass Vaccination Campaigns

#### *Objectives*

Before 1967, the smallpox eradication strategy relied entirely on mass vaccination in the belief that, when the proportion of susceptible persons in the population had been substantially reduced, transmission would cease. Until 1964, it had been assumed that this would occur when 80% of the population had been successfully vaccinated within a period of 4-5 years (World Health Organization, 1959b), an arbitrary figure with no scientific basis. Between 1959 and 1966, mass vaccination campaigns succeeded in eliminating smallpox in a number of countries, but whether 80% of the population had been successfully vaccinated is unknown as little attempt was made to assess the results of the campaigns and knowledge of the numbers of vaccinations performed is of little value because most of the vaccine used was thermolabile and lacked potency, so that many vaccinations were undoubtedly unsuccessful.

The WHO Expert Committee on Smallpox (1964) declared the figure of 80% to be insufficient and recommended that the goal should be to vaccinate 100% of the population. The only basis for this recommendation was the observation in India that smallpox persisted in some areas despite vaccinations which, in the numbers reported, were equivalent to 80% or more of the population. The Committee, however, ignored the information from field studies in India itself (later critically examined by Gelfand, 1966), which showed that the proportion *successfully* vaccinated fell far short of 80% because of the use of subpotent vaccines and the frequent revaccination of the most easily accessible groups. The proposition that smallpox could be eliminated by successfully vaccinating 80% of the population was thus discarded but on scientific evidence just as inadequate as that on which it had originally been based.

The WHO Handbook also recommended that mass vaccination campaigns should aim

at successfully vaccinating 80% of the population. The figure was an arbitrary one, intended only to indicate what could reasonably be expected in a well-conducted programme.

One can only speculate as to how many countries might have succeeded in interrupting transmission simply with an effective mass vaccination campaign reaching 80% or more of the population. However, from the authors' review of programmes conducted after 1967, it would appear that mass vaccination alone resulted, or probably would have resulted, in the elimination of smallpox in South America and most African countries but not in the densely populated countries of Bangladesh, India, Indonesia and Pakistan. Even in America and Africa, however, surveillance programmes were necessary, to provide the basis on which to be able to certify that transmission had been interrupted.

#### *Administration*

The mass vaccination campaigns were conducted by national health staff, usually with technical advice and material assistance from WHO and other agencies. A full-time programme director and unit were usually made responsible for the programme; in the larger countries, special units were also created at state or provincial levels. The programme staff were an integral part of the health ministry and worked with existing health service units, coordinating their activities whenever possible with those of other special programmes, such as those for BCG vaccination, malaria eradication and leprosy and yaws control. Their salaries were paid by the respective governments, although in some cases WHO supplemented the salaries of some senior staff to enable them to work full time in the programme. In most countries, international assistance bore the costs of all supplies and equipment as well as living allowances and travel costs for surveillance teams and the costs of petrol and vehicle repairs. After 1973, when many temporary workers began to be employed to intensify programmes in the remaining endemic countries of Asia and eastern Africa, their salaries were also met by funds from international assistance.

#### *Preparations*

The necessary preparations for a vaccination campaign could be completed within a matter

of a few weeks or a month or two, but most programmes did not begin until 6-18 months after an agreement had been signed between the government concerned and WHO. The length of the delay was usually determined by the time required to deliver the necessary vehicles, but also sometimes by a lag in the allocation of government funds for salaries. During this period, information regarding the past history of smallpox in the country was obtained, demographic data and maps were collected, and staff were selected and trained. As has already been noted, the compilation of the smallpox data available from state and provincial offices and other sources often revealed more cases than those recorded in statistical offices and officially reported to WHO. The compilation of such data made better baseline information available for use in deciding on priority areas for vaccination and in gauging subsequent progress. Except in areas in which malaria eradication programmes had been conducted, the existing maps were generally inaccurate and demographic data often at considerable variance with what programme operations later revealed. Nevertheless, such maps and data were useful as points of departure, changes being made in them as the programme progressed and additional information was obtained.

The supervisors and vaccinators for the programme were mainly health personnel who had previously been engaged in smallpox vaccination or who had been transferred from other field programmes, such as those for BCG vaccination or leprosy or yaws control, which for one reason or another had all but ceased operations. The numbers of health personnel required for the programme were not large and, because underutilization of health personnel in most endemic countries was common, it was seldom necessary for the government to hire additional staff to serve as vaccinators or supervisors. Those who served as vaccinators had usually had at least 6-8 years of education and were sufficiently literate to use forms for recording data. Illiterate vaccinators were also successfully used, especially after 1973, when the programmes were greatly intensified. Supervisors, in general, had had at least 10-12 years of education and had sometimes received additional training in the operation of health programmes.

For most smallpox eradication programmes, special training lasting 1-4 weeks

served to familiarize the staff with the nature of the programme and with their duties and responsibilities. In all but the largest countries staff numbers were sufficiently small to permit close and continuous contact between the senior national staff, the field supervisors and the vaccinators, thus facilitating supervision and a progressive improvement in performance. In larger programmes, and where the staff were widely dispersed, supervision was more difficult and the programmes were generally less effective. During the course of the programme in India over the period 1974-1977, however, an effective method was found for the supervision of large numbers of widely dispersed staff (Brilliant, 1985). A 1-day meeting of senior staff and supervisors was held every month to review performance, progress, strategy and problems. Subsequently, the supervisors and junior supervisors held a similar 1-day meeting and, finally, junior supervisors and vaccinators reviewed the progress in an area served by a health centre. Although the national programme involved more than 100 000 workers, it proved feasible to supervise activities closely and to modify and continually redirect the programme effectively.

Special activities were undertaken to interest and involve health staff based in the outpatient departments of hospitals, in health centres and in similar facilities. In group meetings and during field travel, smallpox eradication programme staff regularly discussed with them the nature and objectives of the programme, emphasized the need to report smallpox cases, and provided supplies and instruction in the proper storage and use of freeze-dried vaccine. Experience showed, however, that in most countries such health staff failed to report cases regularly, usually vaccinated very few of those who attended clinics and seldom undertook to vaccinate people living in nearby houses or villages.

Provision was made for the cold storage of vaccine (at 0-4°C) in the capital city, sometimes in refrigerators belonging to the programme and sometimes in other units used for the refrigeration of meat or vegetables and fruit. Vaccine was also kept at state and district centres in ordinary refrigerators, which were often provided by the programme, the number and location depending on the difficulties of travel and the availability of transport. The distribution system was designed so that vaccine would not be exposed to ambient temperatures for more

than 30 days. In most programmes, however, the maintenance of an effective "cold chain" proved difficult and was often unsatisfactory, usually because of the mechanical failure of refrigerators, interruptions in electrical supply or lack of kerosene. Not infrequently, the vaccine was exposed to ambient temperatures for more than 30 days but because of the high titre and the stability of most vaccines, primary vaccinations were usually successful in 95% or more of the subjects concerned even when the vaccine had been exposed to such temperatures for as long as 6–9 months. Despite failures in the distribution system, unsuccessful vaccinations with properly manufactured vaccine were uncommon after 1967.

Special efforts were made to ensure that vaccination teams and health units always had on hand an adequate supply of vaccine and bifurcated needles. The instructions therefore called for orders to be submitted in advance so that supplies could be replenished well before they ran out, but the system rarely worked well; most units and many countries waited until supplies were exhausted before ordering more. The reserve supplies of vaccine and needles in Geneva, from which

deliveries could be made within 48–72 hours, helped to overcome this difficulty.

Finally, health education materials, such as posters and brochures, radio messages and other media material, were prepared. Although these were used in all programmes, such studies as were done showed that individual discussions with villagers by team leaders, vaccinators or search workers were much more effective in obtaining cooperation and participation.

After the necessary equipment had been assembled and personnel recruited, pilot projects were conducted in most countries. Because mass vaccination was comparatively simple and often familiar, they seldom lasted more than a few weeks or months and were designed primarily for training purposes rather than to test alternative methodologies.

#### *Execution of the mass campaigns*

Most mass vaccination campaigns were designed to be completed during a period of 1–3 years, depending on the size of the country and the number of personnel available. Field activities usually began in areas with the greatest population density and the

highest smallpox prevalence, thereafter moving progressively to adjoining areas. In practice, it was found best to begin the campaign in an area in which vaccination was readily accepted by the population and the logistics were simplest, and to move to more difficult areas when operational systems were well established.

Most countries used mobile vaccination teams; they varied in size but usually consisted of 2-8 persons, each team being given a vehicle. For ease of supervision and supply and to economize in transport, groups of 4-8 teams usually worked in contiguous areas under the direction of a senior health supervisor. The teams usually worked without interruption for 3 weeks, followed by 7-10 days' rest. A useful tactic, but one seldom used, was for a team of 2-3 supervisors to move from area to area and to employ local health staff to assist them. Having individuals on the team who were familiar with the people and the area and who spoke the local language enabled better vaccination coverage to be achieved. Although wider use of this approach would have been desirable, the necessary cooperation of the local health staff was usually difficult to obtain.

If work continued throughout the year, 250 days of field work were possible, but 150-200 were more usual. In some Asian countries in particular, religious and national holidays were frequent and often prolonged; in others, effective field work during the seasonal rains or the hottest months was difficult, if not impossible.

Work schedules had to take a number of factors into account. Nomads, for example, were often widely dispersed during most of the year but would congregate at certain sites to graze their animals or to assist in the harvest during a comparatively brief period. In rural areas, farmers busy in the fields avoided vaccination for fear of the resulting fever and sore arm; better coverage was therefore achieved by vaccinating during slack periods in the agricultural calendar. Special programmes had to be scheduled to vaccinate people attending religious festivals, as in the Indian subcontinent and in many Muslim countries, where thousands or even millions of people often forgathered. Programmes for refugees and migrant seasonal workers were also important. The time of vaccination also had to be taken into account. If vaccination was offered, for example, from 9 o'clock in the morning to 5 o'clock in the

afternoon, large numbers of persons were usually away from their villages—in the fields, at school or at markets. Vaccination in the early morning and in the evening resulted in better coverage but such a schedule was often difficult to arrange.

Two basic approaches to mass vaccination were employed. Throughout Africa and South America, the assembly-point system, in which many subjects for vaccination gathered at a designated site, was well accepted and therefore widely employed. In Asian countries, house-to-house visits were usually made by vaccinators, although large numbers of persons were sometimes vaccinated at places such as railway stations, ferry crossings and refugee camps.

*Assembly-point vaccination.* At an assembly point, many people could be vaccinated by a few vaccinators in a short time if the local leaders lent their support. That support was usually sought by an "advance man" attached to the mobile teams, who visited the area concerned one or more days before the team was to arrive in order to meet the leaders, explain the nature of the programme, and enlist their support in assembling the people and controlling the crowd.

Jet injectors had been expected to be of especial value in campaigns using the assembly-point method, but their potential was seldom realized. With very well organized assembly points 1000-1500 persons an hour could be vaccinated using a jet injector but it was difficult to assemble and to vaccinate so many persons for more than a few hours each day. Because the great majority of the population lived in small, widely scattered towns and villages, the travel of the teams and the preparations at each individual site took a good deal of time. In practice, a team of 2 vaccinators using jet injectors averaged only 1500-3000 vaccinations a day, much the same as the number performed by 3 vaccinators with the much simpler bifurcated needles. Thus, in most circumstances, bifurcated needles were preferred.

The assembly-point system was usually effective in obtaining coverage rates of 80% or more wherever local support was reasonably good and even higher rates when smallpox was known to be present in the area. In rural areas, the best coverage was obtained when the assembly points were so situated that no one had to walk more than 5 kilometres, and preferably no more than 2

**Plate 10.26.** An "advance man" meets with village elders in Ethiopia to demonstrate vaccination and to explain the programme.

kilometres. Otherwise, many individuals were missed, especially children who were too young to walk very far or too old to be carried over long distances. In cities and towns, assembly points were much more closely spaced.

At the assembly points, police or village leaders were needed for crowd control, especially in areas in which the people were not accustomed to orderly queuing. Special measures also had to be taken to prevent the crowds from pressing in around the vaccinators to watch what they were doing. This was usually effected by arranging for the line of people to be vaccinated to pass through a building or between specially erected fences. The information recorded about each person vaccinated was kept to a minimum. Although some health authorities insisted initially on registering each individual by name, age, sex and place of residence, they soon discovered that this made the clerical task too burdensome and that the records compiled were of little or no value subsequently. A simple vaccination tally sheet (Plate 10.27) was commonly used to record the number of vaccinations performed by age group.

*House-to-house vaccination.* In most of the endemic countries of Asia, vaccinators cus-

tomarily went from house to house, and this practice was continued throughout the programme. To many health officials, systematic and orderly house-to-house visits seemed more likely to ensure high levels of vaccination coverage than asking people to gather at assembly points. The method, however, had certain intrinsic drawbacks which generally resulted in a lower rate of coverage. Since fewer persons could be vaccinated in a day than at an assembly point, larger numbers of vaccinators were required. They were often more poorly paid, less strongly motivated and therefore less reliable than the assembly-point vaccinators. They were also widely dispersed, so that it was difficult to supervise them, or even to determine whether they had worked at all. The household members, since they did not know when the vaccinators were going to call, were often absent, and resistance to vaccination was more frequent when families were approached one by one in this manner than when they were part of a large crowd in the carnival type of atmosphere associated with the assembly-point method. During the global eradication programme, well-supervised house-to-house programmes were conducted in some high-risk areas of Asian countries, but were seldom assessed. In most areas, traditional practices continued, indivi-

dual vaccinators being assigned responsibility for populations ranging from 5000 to 20 000 but seldom vaccinating more than 25-50 persons a day. As is described in Chapter 15, the system was costly for what it achieved.

Smallpox vaccination was generally well accepted throughout the world, even among many groups with little prior contact with health services. Groups which resisted vaccination tended to make the greatest impression on programme staff and their importance was magnified by virtue of the time and energy needed to vaccinate them. The older adults, especially women, often objected to vaccination on the grounds that they were already immune, which, in fact, most were. However, for a team trying to contain an outbreak and therefore to vaccinate everyone in the area, the older women in particular were a continual source of frustration. Some orthodox religious groups objected to vaccination on principle; on several occasions this resulted in outbreaks difficult to control. However, the numbers involved were seldom large and, through religious leaders and government officials, most people could eventually be persuaded to accept vaccination. Where variolation was practised, as in the mountainous areas of Afghanistan and Pakistan and in Benin, Togo and western

Nigeria, variolators, as well as some members of the population, objected to or actually forbade vaccination. Except in the more remote areas of Pakistan, however, it was eventually possible to persuade most of them to accept it.

The largest group to resist vaccination were the Amharas of the highland plateau area of Ethiopia. To most Amharas, vaccination was unknown and neither religious leaders nor government officials were able to influence their attitudes significantly. Because only the mild variola minor form of smallpox was prevalent in the area, they did not fear the disease, even when outbreaks occurred. Many methods were used to enhance their acceptance, including that of providing drugs against other diseases after successful vaccination, but large numbers of people still refused. Fortunately, resistance was by no means universal and smallpox transmission gradually ceased in this widely dispersed population.

The simultaneous administration of one or more antigens in addition to smallpox vaccine was known to be both safe and efficacious as well as economical of transport and personnel. For this purpose, however, additional resources had to be made available for the programme and changes in operational procedures introduced. This proved possible in a number of control programmes. In

western and central Africa, measles vaccine was given to all children between 6 months and 4 years of age; in some programmes yellow fever vaccine was also given to persons of all ages; and in others, BCG vaccine was administered, usually to those aged 0-15 years. In many countries of eastern and southern Africa, both smallpox and BCG vaccines were given from the beginning of the programme and, in Afghanistan, diphtheria, pertussis and tetanus (DPT) vaccine and BCG vaccine began to be administered after smallpox transmission had been interrupted.

The question whether other vaccines might be given during the smallpox vaccination campaign did not arise in most countries, however. Up to the end of 1977, when the mass campaigns had concluded, few of the endemic countries routinely provided other vaccines because they lacked the foreign currency to buy them and little was contributed by international agencies. BCG vaccine, which UNICEF provided to a number of developing countries, was an exception. It was difficult, however, to conduct a programme for the administration of both BCG and smallpox vaccines, since the former was usually given by a more time-consuming method—intradermal injection using a syringe and needle. In Africa, vaccinators could routinely administer 500 or more smallpox vaccinations a day using bifurcated needles but only 100 or so BCG vaccinations. To give both vaccines together required either a substantial expansion in the size of the teams—difficult because of the limited transport available—or a much slower-paced programme and inevitably a delay in interrupting smallpox transmission.

To facilitate the development of combined smallpox-BCG vaccination programmes, the Smallpox Eradication unit in Geneva promoted studies of the feasibility of administering BCG vaccine with the bifurcated needle and with the jet injector. While the results obtained with the bifurcated needle were equivocal or poor, those with the jet injector were quite satisfactory. Where jet injectors were used—in Zaire and many countries of western and central Africa—the two vaccines were administered at the same time but inoculated into different arms. Except for the constant difficulty of ensuring an adequate supply of BCG vaccine, these programmes generally functioned well.

Although an effective mass campaign for the simultaneous administration of different

antigens was difficult to start, the feasibility increased as experience was gained and an administrative structure developed. It seemed logical and desirable to the WHO Smallpox Eradication unit to encourage the transformation of the programme, as smallpox began to be eliminated, into one for the provision of other antigens as well. DPT and poliomyelitis vaccines were the best candidates, as the diseases concerned posed problems in the developing countries and the vaccines were inexpensive and as yet little used. Donations of vaccine would, however, have been needed as well as additional staff at Headquarters to develop plans, mobilize resources and provide training. Efforts were made in 1970 and later to persuade senior WHO staff of the desirability of this approach, the importance of timely action increasing as one country after another became free of smallpox and began to dismantle its programme. There was, however, resistance to the development of what was seen as yet another "vertical" programme until 1974, when the Twenty-sixth World Health Assembly decided to establish the Expanded Programme on Immunization. By then, smallpox eradication had proceeded so quickly that a number of national vaccination programmes had ceased to function.

On balance, the mass vaccination campaigns were remarkably successful in most countries, high levels of acceptance and coverage being attained in almost all in 3-4 years or less. The campaigns cost most countries no more than they had been spending on their regular control measures. As the chapters on field operations will show (Chapters 12-22), the assembly-point system of vaccination did not require large numbers of national personnel and international support usually amounted to no more than US\$0.07-0.25 per head of population over the course of the programme. The mass campaigns were, moreover, politically attractive, in some areas providing an important link between the people and the government—sometimes virtually the only one.

#### *Maintenance vaccination by the health services*

At the conclusion of their mass vaccination campaigns, most countries planned for continuing programmes of maintenance vaccination to be provided by the existing health services. Health units were requested to ensure the vaccination of newborn infants

and of children at health clinics and at school entry and to undertake periodic community-wide vaccination campaigns, but the outcome was seldom satisfactory. In all countries, large numbers of people visited health units daily for treatment but the opportunity was rarely taken to vaccinate them. When health centres were inspected, vaccine was regularly found which had been reconstituted days or even weeks previously and continued in use even though stored without refrigeration. Many of the vaccinations performed were probably unsuccessful but in few centres were subjects checked to see what the results had been.

After the mass campaigns, the levels of vaccinal immunity declined steadily in almost all countries, as was documented during surveys conducted for certification purposes. Although not the intention, this proved, paradoxically, to be helpful in the certification process; with large numbers of susceptible persons, smallpox, if present, was more likely to spread and to be detected than it would in a well-vaccinated population.

#### *Assessment*

The WHO Handbook called for "a programme of continuing evaluation of coverage and vaccination take rates by an assessment agent (or team) who is administratively independent of the vaccination team". What was envisaged was a random sample survey of 10-25% of those vaccinated, to be conducted 1-4 weeks after mass vaccination had been completed in an area. The use of an assessor who reported to someone other than the vaccination team leader increased confidence in the reliability of the findings. Although other useful types of evaluation were proposed in the WHO Handbook and were used subsequently in the programme, an ongoing appraisal of this type provided the most important information for use in the quality control of the campaigns. Like surveillance, however, sample assessment was unknown to most health officials and was adopted only with reluctance. Most considered it wasteful of manpower and vehicles to create a team whose sole responsibility was to check the work of others. Many were more willing to provide sufficient personnel to re-examine the entire population and vaccinate those without vaccination scars, but this was rarely feasible or cost-effective.

Independent assessment, although not universally practised, was used to good effect in

assembly-point programmes in Brazil and in a number of African countries, as well as in the house-to-house vaccination campaign in Afghanistan. The rationale of the methods and standards deserves comment. For a reasonably accurate appraisal of the quality of work in an area to be made, a random selection of villages was important, however crudely done, otherwise the assessment teams would visit the villages that were most easily accessible by vehicle and therefore the most likely to have the best vaccination coverage. The methods used for random selection varied widely, from a sophisticated approach in Guinea, in which villages were selected within a defined sampling frame and in proportion to population, to a much simpler one in Afghanistan, in which pieces of paper bearing the names of villages in which vaccination had been performed were placed in a box and the specified number drawn at random. The method of sampling was less important, however, than the fact that sampling was done and that teams were aware that their work was regularly checked and that, if the results were unsatisfactory, more work would be required. Most took pride in being able to meet or surpass the established goals.

The assessment teams also evaluated the efficacy of the vaccine that had been used, but only in the case of primary vaccination. The primary vaccination lesion was so distinctive that there was never any question whether vaccination had or had not been successful. With revaccination, on the other hand, there were many equivocal responses among persons with partial immunity, and their interpretation differed from observer to observer. Moreover, a standard for successful revaccination was impossible to establish because of the varying levels of immunity in different areas. For primary vaccination, a successful take rate of at least 95% was established as a minimum standard, a figure which permitted a margin of error in recording and observation because take rates normally approached 100% when a satisfactory vaccine was properly applied. The assessment of results of primary vaccination only had the further advantage that the response could be evaluated 1-4 weeks after administration, rather than in the 6-8 day period required to evaluate revaccination responses. More flexible schedules for the assessment teams were thus possible. In all but a few instances, primary vaccination take rates consistently exceeded 95%; where they were found to be

lower, problems of vaccine handling or vaccine quality were usually discovered which could then be rectified.

Coverage after a campaign was measured in terms of the proportion of the population with a vaccination scar or with evidence of recent primary vaccination rather than in terms of the proportion vaccinated during the campaign. It was simpler and more reliable to inspect a person, particularly a child, for the presence or absence of a vaccination scar or lesion than to ask whether the subject had been vaccinated during the team's visit. This simplified method was feasible because vaccinal immunity was so durable in endemic areas, even after a single primary vaccination. The standard of performance originally set by the WHO Handbook was that not less than 80% of the population should show evidence of immunity, as indicated by a vaccination scar. In most programmes, levels of 90% or more were common, the highest rates being among adults and older children. With time the methodology was changed so that in most countries only children under 15 years or even under 5 years were examined, but the criterion was retained that not less than 80%, and sometimes 90%, of that age group should have a vaccination scar or lesion. This approach was operationally advantageous because children were more likely than adults to be found in or near their homes when a visit was conducted. Given that older age groups consistently had even higher levels of coverage than the younger ones, a standard requiring evidence of immunity in 80% of children effectively ensured an overall population immunity of more than 90%.

The assessment data provided information on performance, but they were also used to guide operations, which was just as important. When it was found that vaccination coverage was below standard, teams were usually required to return to the area, sometimes without the payment of travel allowances, to revaccinate the entire population.

Other forms of assessment were also employed in the mass vaccination campaigns. One, used almost everywhere, was to compare the number of vaccinations performed in an area with the estimated resident population. This provided a rough indication of the success of the campaign but an unreliable one because the available population data for small localities were often highly erroneous

and often many non-residents were also vaccinated. In some areas of western Nigeria, for example, where the number of vaccinations reported to have been performed corresponded to 80% of the population, sample surveys later showed that fewer than 40% had vaccination scars.

Another approach was to enter the names of all residents and their vaccination status in a register (as in India) or on cards (as in Zaire), in the expectation that, after the vaccination team had left, health staff could refer to the records and vaccinate those who had been missed. The preparation of such records, however, was exceedingly time-consuming; keeping them up to date proved all but impossible; and the effort required to find and to vaccinate every person who had been missed was prohibitive. All countries which endeavoured to register the names of vaccinated subjects soon abandoned the practice as being impracticable except the United Republic of Tanzania. There, what were called "ten-cell chairmen" prepared a list of all the inhabitants of their assigned area and, when vaccination teams arrived, called individuals forward one by one for vaccination. There were few countries, however, in which political or other organizations could assume such a burden of clerical work, and even in the United Republic of Tanzania the information was not retained as a permanent record.

Sample surveys to assess the status of immunity of selected population groups were undertaken periodically in a number of programmes. Such surveys proved useful for deciding on vaccination strategies for special groups and, on a larger scale, were important when it came to certifying the absence of smallpox. National and other large-scale surveys were performed in western Africa and in India but they proved of little value. National and, in Nigeria, regional surveys, conducted in western Africa in 1969-1970 to measure overall programme performance, revealed problems in some areas, but the information was obtained so long after the campaign had been conducted that the specific causes of the problems could not be identified nor corrective measures taken (see Chapter 17). In India, the forms and assessment methodology used in Afghanistan (see Chapter 14, Plate 14.3) were introduced in some states. It was hoped that health officers responsible for the house-to-house vaccination campaign would identify areas and

populations which had not been well vaccinated and would take corrective action. Although tens of millions of people were examined in the course of assessment exercises, most health officers saw the activity as an end in itself and took no action to correct problems. Large-scale surveys of this kind were gradually abandoned.

Progress in national programmes had traditionally been measured by the numbers of vaccinations reported each year. The data, compiled by administrative units, continued to be collected throughout the course of the programme but varied considerably in quality. In most areas, the vaccinations actually performed were counted, but in some, the numbers reported were equivalent to the assigned goals, while in others, they were estimated on the basis of the quantity of vaccine used. As the programme progressed, these data received less and less attention and greater emphasis was placed on trends in the numbers of reported cases of smallpox. By the early 1970s, data on the numbers of vaccinations reported each year and in each country ceased to be compiled in Geneva and, by the mid-1970s, interest in them was largely confined to the media, which regularly inquired about the numbers of vaccinations being performed. It proved preferable to give the reporters some estimate than to attempt to explain why such data were no longer available.

### *Legislation*

Legislation on smallpox and vaccination existed or was adopted in most countries, but in most instances it proved to be of little benefit other than as an official statement of policy. In the majority of countries, legislation was enacted which called for compulsory vaccination at or shortly after birth, periodic revaccination, and the mandatory isolation of patients; some countries prohibited variolation and required citizens to report cases of smallpox. On the few occasions when action was taken to enforce such laws, the results were poor and often counterproductive. In India, for example, attempts to levy fines on persons who refused to be vaccinated led to protracted proceedings in the courts without any apparent increase in compliance by the general public. The forcible isolation of patients in hospital often caused many families to hide infected household members and impeded effective containment measures.

The prohibition of variolation may have caused some variolators to abandon the practice but in Afghanistan, for example, it resulted in the general public refusing to supply information about them, making it more difficult to identify them and to persuade them to cease their activities.

Other forms of coercion, however, were occasionally needed and effective in special circumstances. For example, in crowded refugee camps, the rule that all persons should be vaccinated before being given food ensured rapid and complete coverage; during containment vaccination, a police presence often discouraged resistance to vaccination; and in Botswana the government's threat to expel a religious group from the country secured cooperation in accepting vaccination when other measures had failed.

### **The Surveillance-Containment Strategy**

The history and rationale of the surveillance-containment strategy have been described earlier, as has its implementation at the global level. At the national level, the foundation for implementing the strategy was the network of reporting posts making up the national reporting system, complemented by mechanisms for the prompt investigation of cases and the containment of outbreaks. The WHO Handbook stressed the importance of establishing or strengthening a reporting network from the inception of each national programme but postulated that, in countries with a high incidence of smallpox, the available resources would not immediately permit the investigation and containment of all outbreaks. Although the Handbook recommended that a reporting system should be established in all countries as soon as possible, it proposed that, in countries reporting more than 5 cases per 100 000 population, case investigation should be limited to major outbreaks and to those in areas in which mass vaccination had been completed. In other countries, all cases were expected to be investigated and containment measures taken. In mid-1967, the data available showed that only 13 of the 31 countries in which smallpox was then endemic had rates of 5 per 100 000 or more, of which 6 were in western Africa (Dahomey (Benin), Mali, Niger, Nigeria, Sierra Leone and Togo), 4 in eastern and southern Africa (Burundi, Uganda, United

Republic of Tanzania, and Zaire) and 3 in Asia (India, Indonesia and Pakistan).

The belief that it would be some time before all reported cases could be investigated and contained rested essentially on 3 premises which, in most of the endemic countries, proved to be incorrect. The first was the notion that the level of vaccinia immunity in the population was universally low, especially in countries with a high smallpox incidence, and that mass vaccination would be necessary before the numbers of cases decreased sufficiently to permit each to be investigated. Overall vaccinia immunity in some countries was indeed low and mass vaccination campaigns did serve to reduce incidence, notably in Afghanistan, Brazil, Ethiopia, Nepal, northern Nigeria and Sierra Leone. In 1967, however, half or more of the population of most countries were found to have vaccination scars, and among these countries were some which reported a substantial proportion of all cases. In India, Indonesia and Pakistan, more than three-quarters were already fully or partially immune because of past disease or prior vaccination. It was found there that the interruption of smallpox transmission was less closely related to an increase in the proportion of the total population with vaccinia immunity than to better reporting and containment measures. The second misconception was that, where smallpox incidence was high, cases would be so numerous and widely scattered that a great many teams would be required to investigate and contain the outbreaks. With few exceptions, it was discovered that smallpox cases, although far more numerous than reported, were clustered in comparatively small areas, so that relatively few surveillance teams were needed to investigate and contain them. Finally, it was believed that, in most countries, health units were so few and so scattered that reporting systems would have to be based primarily on reports from village leaders, teachers and the like, and that these systems would require considerable time and substantial manpower to establish. In fact, most countries, even many of the least developed in Africa, had a remarkably extensive network of health posts and far larger numbers of health personnel than the WHO Smallpox Eradication unit had expected.

Soon after the Intensified Programme began, it became apparent that surveillance-containment programmes could be developed reasonably quickly and that such systems

could rapidly interrupt transmission. The findings in East and West Pakistan in the years 1965-1968, in eastern Nigeria in 1967 and in Tamil Nadu State (India) in 1968 showed that:

(1) The reporting of cases, although incomplete, was usually adequate to identify most large outbreaks; many other cases could be readily discovered by a few field teams through the investigation of reported cases and by questioning health staff and villagers.

(2) Patients with smallpox usually transmitted the disease to very few people and only to those in close face-to-face contact. Transmission in markets or schools, for example, was uncommon. Outbreaks therefore tended to be clustered among acquaintances in certain parts of a city or areas of the country rather than being widely and randomly dispersed.

(3) Only persons with a rash were able to transmit infection to others; this made it comparatively simple to trace the chain of transmission from person to person.

(4) Where, as was the case in most countries, there was significant seasonal fluctuation in smallpox incidence, few persons or villages were infected during the season when transmission was at a low level; the discovery and containment of outbreaks during this season substantially reduced the number of cases in the subsequent smallpox season.

(5) Outbreaks could be easily and rapidly contained in most areas with a high degree of success by isolating the patient and vaccinating contacts and most persons in the immediate vicinity.

Given also that smallpox was so distinctive that it could be diagnosed reasonably accurately by villagers themselves, that there was an incubation period of fully 10-12 days between cases, and that the vaccine provided more durable protection than had been believed, the conditions for an effective surveillance-containment programme were unusually favourable.

Nevertheless, however logical and attractive the surveillance-containment strategy appeared to be, it was not readily accepted by programme directors. In part, the difficulty lay in understanding and accepting what seemed to be a simple concept—that all cases of smallpox were links in an identifiable continuing chain of infection and that, in every area, there was a finite, usually small

WHO: N. WILLIARD

**Plate 10.28.** Careful questioning of villagers could usually reveal the source of infection of the first case in an outbreak of smallpox, but it was not always easy to tell from their directions where and how far away the person concerned might be.

number of chains. If a 2-week interval between cases is assumed, a single chain of transmission in a country would result in not less than 25-50 related cases in the course of a year. Even in countries with many cases, the number of chains of infection would not be large; a country with 500 cases a year would have no more than 10-20 such chains. Because the cases were so closely related to one another, the strategy required not only the containment of each outbreak but also the discovery of the antecedent cases and outbreaks in the chain and their containment. The lack of comprehension of this principle during the early years of the programme was indicated by the frequent reference by many programme directors to the occurrence of "sporadic" cases rather than to cases whose source of infection could not be found.

At the outset it was difficult to convince the authorities of the usefulness of setting up surveillance teams staffed by competent senior health personnel, although many created "fire-fighting teams" of poorly supervised vaccinators whose task was to adminis-

ter vaccine when epidemics were discovered. Even when demonstration programmes were conducted by its most enthusiastic proponents, the surveillance-containment strategy was slow to gain acceptance. In western and central Africa, Dr William Foege and his colleagues tried to introduce it from the summer of 1968 but, as is recounted in Chapter 17, northern Nigeria, the most heavily infected area, did not participate. In 1968 and 1969, Dr A. R. Rao enthusiastically described his successful experience in interrupting transmission in Tamil Nadu State (see Chapter 15), but he did not succeed in persuading other state programme directors in India to follow his example; in Brazil, the achievements in 1969 of Dr Ciro de Quadros and his colleagues were likewise disregarded (see Chapter 12). Precisely when country-wide surveillance-containment programmes were fully implemented is difficult to say, but approximations are possible for the most populous countries. In the endemic countries, the first were those in western and central Africa, which began late in 1968. These were followed by Afghanistan and Indonesia in 1969, East Pakistan in 1970, Brazil, Ethiopia and Zaire in 1971, Botswana and the Sudan in 1972, India, Nepal and Pakistan in 1973, and Somalia in 1977.

Before 1973, simple surveillance-containment measures were employed, and these are described first in the following sections. From 1973 onwards, with global eradication closer and more resources available, the techniques became increasingly sophisticated; that period is discussed later in this chapter.

#### *Routine notification of cases*

The foundation of the surveillance system was a weekly report from each health unit which documented the number of smallpox cases seen that week; if none was found, a report showing "nil" had to be sent. To simplify and encourage reporting, only the most basic facts about the patients were requested: name, age, sex, village (or urban district), date of onset of rash, and whether the patient had previously been successfully vaccinated (as shown by the presence of a scar). The information could be contained in one line on a form and the report was therefore termed a "line listing of cases". These reports were to be dispatched at the end of the week to an intermediate administrative

unit (a state or province in smaller countries, a district in larger ones) and so on up the echelons, eventually reaching the national programme office. Each week, the national office reported to WHO Headquarters by telex or by mail the number of cases of smallpox by week of report and by district and state or province.

The system was designed to provide only the information that was relevant to programme operation at each administrative level. To check that the system was operating correctly, all units at each administrative level were expected to submit a report whether or not cases of smallpox had been detected. Numbers of deaths were not requested because progress in the programme was monitored in terms of smallpox incidence; the action to be taken, such as investigation and containment, was related to the occurrence of cases rather than of deaths. The information provided by the line listing, which was necessary for the investigation of cases by the surveillance teams, was of the greatest value at state or provincial offices in smaller countries or district offices in the larger ones. To facilitate the transmission of data by telegram or telex, higher-level administrative authorities received current data only on the numbers of cases by administrative unit. More detailed epidemiological information was usually collected and analysed nationally, but at a later stage.

In the notification system, all cases, irrespective of date of onset, were supposed to be recorded according to the week in which they were detected. In most countries, this meant the week in which they were seen by the health unit. A record system of this type was simple to operate and worked far better than one in which an attempt was made to record and tabulate all cases according to week of onset of illness.

In 1967, reporting practices varied widely from country to country; none followed precisely the pattern described above, but many had a reporting structure by which each health unit provided some sort of report weekly or monthly. This often entailed notifying cases of 25-50 diseases together with a variety of data on the operations of the health units. The reports were seldom used for operational or supervisory purposes and efforts were rarely made to ensure that they were submitted promptly or even that all units reported. At intermediate administrative levels, the situation was little different.

Special notification systems were sometimes prescribed for the diseases subject to international quarantine regulations, such as smallpox. Some required village leaders and others who became aware of a case of the disease to report it to the responsible administrative authorities, but this was seldom done. Telex or telephone notification of the quarantinable diseases to national or provincial authorities was also requested in some countries but, again, not consistently carried out. With smallpox, there were other problems. Some health units diagnosed mild cases as "variola minor", considering them not to be "true smallpox", and did not report them. Where, as in India, the occurrence of cases was taken as evidence by supervisors that the vaccination campaign had been inadequate, health units suppressed reports of cases. In all countries, there was such substantial underreporting that it is not surprising that many countries believed smallpox to be a much less serious problem than it was.

The development of fully satisfactory notification networks took not less than 1-2 years. In many countries, this was facilitated by epidemiologists or mobile surveillance teams, each of which could usually cover an administrative area with a population of 5-10 million. The teams regularly visited each health unit to explain the programme, emphasize the need to report cases, encourage vaccination, distribute forms and vaccine, and check on late reporting. When cases were reported, the team investigated and contained the outbreaks, sometimes with the help of those at the health unit, and usually discovered many additional cases in the process. The frequent visits to the health units by the mobile teams and their prompt response when cases were reported proved to be a great stimulus to reporting, especially because other supervisory health staff rarely visited health units. Interest was also stimulated by national surveillance reports, published weekly or monthly in many countries and distributed to health staff at all levels.

Of the many problems encountered in developing the notification network, two deserve mention because of their relevance to the development of systems for other diseases. The first was the difficulty of persuading health authorities of the need to receive regular weekly reports, even when no cases were found. Most assumed that if no report was received, no cases had been detected. Experience showed, however, that the units

that failed to submit reports were usually the least effective in performing functions of all types, including vaccination. It was in such areas that large, hitherto unknown epidemics were the most frequently discovered. The second problem, encountered only in India, related to the decision by government authorities to record all cases according to week of onset rather than week of report. This resulted in chaotic record-keeping at all levels of the health system and contributed to a significant underreporting of cases (see Chapter 15).

Reporting units, even in the smallest countries, numbered 100 or more, and in countries with large populations, more than 1000. In India, the largest of the endemic countries, there were no fewer than 8167 units reporting weekly to 397 district offices, which, in turn, reported to 31 state programme offices, and these to the national programme office in New Delhi.

#### *Other mechanisms for case detection*

Routine case notification by health units, however assiduous, provided only incomplete data on numbers of cases. While such data were useful when deciding on the allocation of resources and as a point of departure for field investigations, additional measures were required to detect most and eventually all existing cases. For various reasons, patients did not always go to health units: some lived too far away; many, especially with variola minor, were not sufficiently ill to seek medical attention; some believed, rightly, that therapy would be of little value; and some wished to avoid detection so as to escape, for religious or cultural reasons, compulsory hospitalization or vaccination of household contacts. Not surprisingly, few patients came to health units in areas in which their dwellings were burnt as a prophylactic measure.

Help in detecting cases was sought from other health staff as well as from the government and private individuals. Health workers who moved from village to village in the course of family planning, malaria, leprosy or yaws control programmes should have been a useful source of information, but few contributed significantly until a reward was offered for detecting cases of smallpox. At different times and in different countries, appeals to report suspected smallpox cases were also made to administrative officials,

religious leaders, development officers, agricultural extension workers and police and security forces; although many were helpful in other ways, their assistance in reporting on smallpox was minimal.

The most effective mechanism for detecting cases not seen at health units was the field investigation of the cases which had been reported. This was usually one of the first measures to be undertaken as surveillance programmes developed. Because the spread of smallpox tended to be limited to close personal contacts, many additional cases could usually be quickly discovered among the family and village or neighbourhood contacts of a case. By careful questioning of the patients, sources of infection in other villages could be identified and investigated. In Brazil, for example, the investigation of each reported case brought to light an average of 50 other cases.

As the Intensified Smallpox Eradication Programme progressed, it became apparent that the discovery of cases through routine reporting and the investigation of outbreaks were still inadequate. Many outbreaks were large by the time they were found and had already spread to other areas. Monthly or semi-monthly visits to all villages would have served to detect cases earlier, but in most countries it would have taken a year or more to visit every village, even briefly, given the number of the smallpox eradication staff.

Methods were therefore required to permit the staff to search rapidly for cases over wide areas. Among the first of the methods developed were inquiries by workers in schools and markets. Schoolchildren proved to be an exceptionally good source of information, being well informed as to who in their villages was ill and with what diseases and tending to be more forthcoming with information than adults. Surveillance teams were able, in a brief visit to a school, to question children from villages as distant as 5-10 kilometres. This approach, developed in Indonesia in 1969 (see Chapter 13), eventually became standard practice in all surveillance programmes. Akin to this approach was the questioning of those attending weekly markets.

When the numbers of outbreaks in a country or area decreased to very low levels, it became possible to search for cases among those who had been exposed to patients but had left the area. Tracing such contacts was difficult and not especially productive: com-

paratively few contacts became ill, since many were already immune or had not been sufficiently exposed to become infected. This technique was seldom used, therefore, even when there were few outbreaks.

The techniques for case detection described above were adequate for programmes in most countries of Africa and South America as well as some in Asia, but in the densely populated areas of Asia additional measures were adopted. Village-by-village and even house-to-house search became possible when additional staff could be recruited. The first village-by-village search was conducted in Indonesia in 1969 and the technique was employed thereafter in high-risk areas (see Chapter 13). It began to be used in India in 1972 and was extended nationally in 1973 (see Chapter 15). It then became the standard practice in the remaining endemic countries.

#### *Data analysis and surveillance reports*

Important elements of the surveillance process, as described in the WHO Handbook, were "the concurrent analysis and interpretation of reported data and studies" and the "widespread dissemination of the compiled and interpreted data to principal reporting sources and to others concerned with disease control activities". Although such activities might appear to be logical and routine in any systematic data collection process, they were uncommon at first in the endemic countries. This reflected, in part, the fact that progress in smallpox programmes had been measured by numbers of reported vaccinations rather than by numbers of cases of smallpox, and, in part, the disdain commonly felt by health officials for routinely collected morbidity data, which are everywhere recognized to be incomplete. Rather than using the information that was available, while at the same time trying to improve the system, such officials took little notice of the data.

Routinely collected morbidity data, incomplete and biased though they may have been, proved of value from the beginning of the programme and, as they improved, became ever more useful. Vaccination campaigns in most countries began in the areas that reported the largest number of cases and, in some, smallpox was eliminated before the national campaign came to an end. When cases were found primarily among children less than 15 years of age, the campaign

strategy was altered to focus particularly on the vaccination of children. The early observation that most cases of smallpox occurred among persons who had never been vaccinated led to the studies previously mentioned which showed that vaccinal immunity was far more long-lasting than had been appreciated and to a consequent emphasis on primary vaccination. Many other illustrations of the usefulness of morbidity data could be offered.

In addition to the international surveillance reports, already described, national surveillance reports were also prepared and had a major impact on the various programmes. The first of these was a weekly mimeographed report, which was started in Brazil in 1967 (see Chapter 12). When special surveillance teams began discovering large numbers of unreported cases, it described what appeared to be a developing epidemic and this in turn attracted the attention of the press together with renewed political commitment and increased resources.

#### *Containment*

The containment of an outbreak was, in principle, straightforward, calling for isolation of the patient, vaccination of the members of his household and other contacts, investigations to determine if there were other cases in the area and identification of the source of the outbreak so that it, too, could be investigated and contained.

Before 1967, the responsibility for, and the methods used in, investigating and containing outbreaks differed from country to country. In most, local health officers were expected to initiate the necessary control measures, although national vaccination teams were sometimes deployed. Where variola major was present, mass vaccination was widely used when large outbreaks occurred, but smaller outbreaks were usually ignored. Special measures were seldom taken against the mild variola minor form. Patients usually remained in their homes or, where hospitals existed, were confined to a smallpox ward or a general infectious diseases ward. Special investigations to identify all cases or to determine the source of infection were practically unknown. If the patient recovered, it was sometimes the practice to disinfect surfaces in the room by scrubbing them with a formalin solution or carbolic soap and to burn the patient's clothing and bedding. In some places the practice was to

**Plate 10.29.** Front of the WHO smallpox recognition card that was widely used from 1971 in endemic countries. Smallpox eradication workers searching for cases would show the card and inquire whether anyone had seen a person with a similar rash.

**Plate 10.30.** Reverse of the WHO smallpox recognition card. It was on heavy-duty A4-size paper and cased in plastic for protection, unlike the pocket-sized version shown in Plate 10.11. In Ethiopia, a variant was used that showed an Ethiopian patient with variola minor.

burn all dwellings in which cases had occurred.

The WHO Handbook devoted only 7 pages to a discussion of proposed containment and disinfection methods; the latter, quoted from Dixon (1962), were impracticable and, indeed, scientifically questionable. For example: "Letters: (a) Iron separate pages, both sides; (b) Expose loose pages and envelope to formalin vapour for three hours, then seal." The Handbook recommended that, in countries reporting fewer than 5 cases per 100 000 population, responsibility for containment should be given to a "knowledgeable person", defined as a trained epidemiologist. It recommended that the patient should be isolated, the source of infection identified, and household contacts vaccinated as well as "several hundred to several thousand persons ... in a brief intensive effort". It had little to say about the practical problems of containment, since there was little information in the published literature and those responsible for writing it had no practical experience of their own.

The diligence with which the containment of outbreaks was pursued after 1967 paralleled, in general, the development of reporting systems. Experience in executing containment measures gradually accrued as the programme progressed, but up to the end of 1973 the measures taken were comparatively simple ones, quite different from the disci-

plined methodology which began to be applied during the concluding stages of the programme in Asia and Africa in 1974.

Field experience showed that the isolation of patients in their own home or in a separate dwelling was usually the best practice. Because there was no effective therapy for smallpox, the hospitalization of patients was of little benefit. Moreover, hospitalized patients frequently spread infection to other patients, visitors and staff because hospital administrations regularly ignored isolation procedures. In fact, the authors are unaware of any institution in any endemic country, except one hospital in Madras (India), in which proper isolation practices were followed until they were introduced by smallpox eradication programme staff. So prevalent was the problem that programme staff often referred to hospitals as "smallpox transmission hospitals". Precautionary procedures were comparatively simple—the vaccination of staff and visitors, the isolation of all smallpox patients in a special ward and the vaccination of all such patients to protect any who might have been misdiagnosed. In most hospitals, however, smallpox patients were regularly accommodated in infectious disease wards with patients with other diseases or, at best, intermingled with chickenpox patients. Visitors usually came and went as they pleased and hospital staff themselves were frequently unvaccinated. Even late in the course of

**Plate 10.32.** Search workers used loud hailer at weekly markets, such as this one in Ethiopia, to seek information about possible cases of smallpox.

national programmes, infection in hospitals continued to occur, the last cases in Brazil and South Africa, for example, having been infected in this way. Indeed, the last case of endemic smallpox, in 1977, was in an unvaccinated hospital employee.

In most countries, the isolation of the patient in his home was both traditional and satisfactory but, in some, social customs led to the infection of many susceptible persons. Among some groups in the Indian subcontinent, for example, it was traditional for relatives and friends to visit those who were very sick, and in Indonesia young children with smallpox were often carried from house to house to be seen and comforted by relatives. Not surprisingly, simple containment measures were ineffective in these areas and smallpox spread rapidly. Interestingly, the most effective practices of patient isolation were found among scattered, illiterate African and Asian tribal peoples, who often arranged for the patient to be housed in a separate dwelling and to be cared for by someone who had previously had smallpox.

Special disinfection procedures after the patient had recovered were uncommon except for boiling or burning the patient's clothing and bedding; hospital rooms were cleaned in the ordinary way. Because few cases appeared to result from contact with fomites, no attempt was made during the programme to alter customary disinfection methods whatever they were.

The vaccination of contacts and the "several hundred to several thousand persons" in the area was fairly perfunctory until the programme was greatly intensified in 1974. Such vaccination was usually conducted during the main part of the day in the course of outbreak investigation. Inevitably, a number of residents, including household contacts, were away from home or their village at this time and so remained unvaccinated. Nevertheless, in Africa and South America, this brief but incomplete vaccination effort was usually sufficient to contain the outbreak eventually, even though one or several generations of cases might subsequently occur. In some countries, as cases became fewer, teams began to vaccinate early in the morning and in the evening to ensure more complete coverage, but seldom was a systematic effort made to enumerate and vaccinate all residents.

Attempts to trace the source of infection were sometimes made but were not always successful, special skills and diligence being required in questioning the patient, his family and friends. It was especially difficult to obtain such information, for example, from persons engaged in illicit activities such as smuggling or from people who had acquired the disease from prostitutes. A few programme staff, however, acquired an unusual mastery of the technique of tracing sources of infection and prided themselves on being able to identify the source of every

outbreak. Conversely, there were some other-wise competent epidemiologists who were consistently unsuccessful in this task; a few, especially early in the programme, simply characterized most cases as "sporadic".

### Surveillance and Containment Measures after September 1973

From September 1973, the nature of surveillance and later of containment measures began to change significantly. By then, comparatively simple surveillance-containment operations and mass vaccination campaigns had been successful in stopping transmission in all but 5 countries—Bangladesh, Ethiopia, India, Nepal and Pakistan. Even in these countries, simple surveillance-containment measures had successfully eliminated smallpox from large areas, including much of southern India, Nepal and Bangladesh. Lack of progress in northern India and Pakistan, however, made it clear that neither country was likely to stop transmission without a more concerted effort. In the summer of 1973, therefore, a more elaborate system for case detection and subsequently for containment was devised by WHO and Indian staff which would involve large numbers of health service personnel, larger numbers of WHO and Indian epidemiologists, and greater financial support. Similar intensified efforts began late in 1973 in Pakistan, early in 1975 in Bangladesh, towards the end of 1975 in Ethiopia, and in May 1977 in Somalia when smallpox again became endemic there following importations.

#### *Surveillance*

In India, the persistence of smallpox despite high levels of vaccinal immunity was attributed partly to the high population density and partly to the frequent suppression of reports of cases by health staff. When, in 1974, the sources of all outbreaks began to be more carefully investigated, it became apparent that there was a third factor of significance—the frequent spread of smallpox over long distances. Of 6227 outbreaks for which the source was identified in 1974-1975, 1129 (18%) were found to have originated outside the state in which the outbreak had occurred and 25 outside the country itself (Basu et al., 1979). By comparison, data from Ethiopia,

fairly typical of the experience in Africa, showed that the source of only 2% of outbreaks was outside the region (province) concerned (Tekeste et al., 1984).

It was believed that the key to eradication in the remaining affected areas was the more complete and the more prompt detection of outbreaks. Accordingly, it was decided to supplement the routine notification system by enlisting the participation of health staff from other programmes in national village-by-village, and eventually house-to-house, searches. Such searches had been shown to be effective in a district and in one state of India during 1972-1973 and, since large numbers of health staff were available in that country, it seemed reasonable to try to undertake them on a national scale. A detailed plan and guide were prepared which called for every inhabited locality in the search area to be visited in order to detect cases or to confirm their absence. In concept the plan was simple. The health staff in each administrative area would each be assigned 1-3 villages to visit each day. With the numbers available, an entire state could be covered within 7-10 days. After the search, the staff of the smallpox eradication programme, assisted by the local health workers, would contain the outbreaks which had been detected.

This proved to be feasible in Pakistan and Bangladesh as well as in India, but in Ethiopia and Somalia, with few health staff, temporary workers were required. Those from local ethnic groups, even the illiterate, who knew the topography and the people, proved to be the most effective—indeed, better than educated persons from urban areas. Considerable numbers were involved in each national search—more than 120 000 in India, 10 000-20 000 each in Bangladesh and Pakistan, and several thousands in Ethiopia and Somalia.

Training and motivating the large numbers of people involved were easier than had been expected. Training sessions of 1-2 days' duration were conducted before each search for personnel at the highest and intermediate administrative levels; subsequent sessions were conducted by intermediate-level supervisors for primary health centre supervisors, and, finally, by these supervisors for all health centre staff. Each intermediate and lower-level supervisor thus attended 2 training sessions, one as a participant and one as an instructor. At each meeting, the method of search was described

and, before the second and subsequent searches, the results and problems of the previous search were reviewed. The forms used were so designed that, when properly filled out, they guided each supervisor and search worker in carrying out his responsibilities.

The searches were conducted at different intervals in different areas—usually once every 4–8 weeks in endemic areas and once every 2–3 months in non-endemic areas. In the interval, additional search programmes were carried out in high-risk areas and in areas in which performance had been poor.

The development of a local search plan, in an area with perhaps 100 000–200 000 inhabitants, was the responsibility of the health officer in charge of that area. He selected the personnel to be employed and, using maps and demographic data, gave each worker 1–3 villages to visit each day on certain specified days. Those conducting the search travelled on foot or by bicycle. Some overlap in the sectors assigned helped to ensure that no areas were omitted. Usually, the workers travelled alone but in geographically difficult or dangerous areas a 2-man search team was used. A supervisor oversaw the work of 5–10 workers.

Through 1974, searches were conducted only in India and Pakistan and, until the autumn of that year, search workers were instructed to contact a number of different persons and groups in each village: the administrative head, postman, watchman and

other local figures; people working in health units; children and teachers in schools; owners and customers of tea-shops; frequenters of markets; and persons at temples, mosques, churches, bus stops and similar places where people gathered in large numbers. The inhabitants of clusters of houses in each of 4 sectors of a village were to be visited, as were those in the poorest area. Although the more diligent workers were able to carry out all these activities, many did so perfunctorily, with the result that a number of cases failed to be detected. Overall assessment of the activities proved difficult, as did the identification of those performing inadequately. In the autumn of 1974, the numbers of cases and outbreaks had decreased sufficiently so that the method of search could be changed to one of house-to-house visits. A reward was offered and each search worker was required to place a poster or to paint a notice publicizing the reward on every tenth house, as well as on the schoolhouse. The quantity of forms, reports and posters required for each national search was considerable, one estimate in India indicating the need for a total of 8 tonnes of paper.

To ensure that the proper questions were asked, each search worker was trained to use a particular approach: he was to introduce himself as a health worker, explain the reason for his visit, show the WHO smallpox recognition card, inquire about suspected smallpox cases and tell the people about the reward and where to report suspected cases.

When a suspected case of smallpox was found, the search worker immediately notified his supervisor or the nearest health unit so that a containment team could begin work. In Ethiopia and Somalia, in which the population was widely scattered, search workers usually carried vaccine and were instructed to begin containment vaccination when a suspected case was found. The periodic discovery of suspected cases was important in sustaining the interest of the workers, but in areas which had become smallpox-free, interest was sustained and a mechanism of assessment provided by requiring them also to look for cases of chickenpox and measles and to detect and report all deaths accompanied by skin rash. This also provided added assurance that smallpox had not returned.

Special searches had to be devised for Somalia and other areas such as the Ogaden desert in which groups of nomads were

continually on the move. As is described in Chapter 22, different approaches were used to ensure the coverage of large areas while at the same time ensuring adequate supervision and assessment. In these areas, teams of 2 regularly walked long distances—50–150 kilometres—usually carrying vaccine so as to vaccinate any nomads encountered.

The organization of searches in urban areas was complex, and ingenuity was needed to coordinate the activities of the many and varied groups who usually participated, including numerous categories of municipal health staff and sometimes medical students, trainee nurses and volunteers from public services.

An intensive publicity campaign before and during the search, including the use of loudspeakers on cars and rickshaws, slides for projection, radio announcements, newspaper articles, handbills and posters, was found to be important in obtaining cooperation. As in rural areas, house-to-house searches were conducted, but schools, markets, factories and private medical practitioners were also visited. Special attention was given to areas in which migrants lived and to poor neighbourhoods. In urban areas, it was found that a search worker could visit 150 houses a day or about 1000 houses a week; 10 search workers with 2 supervisors were required to search an urban area with a population of 150 000.

Continuing assessment of search operations was as important as independent assessment of mass vaccination campaigns, as became apparent after the first search in India. Supervisors reported that 90% of villages had been searched and, indeed, thousands of previously unreported cases were detected, but a separate assessment by surveillance teams discovered that less than half the total had, in fact, been covered. An assessment programme was therefore developed which provided for independent appraisal of 5-20% of the localities by higher-level health officials and special teams. Where it was found that less than 85% of villages or urban sectors in an area had been searched, the entire search process was repeated in that area. As time passed, the minimum standard was raised to 90% and the areas chosen for assessment were deliberately selected to include those least likely to have been well covered, such as the villages furthest from health units and those with a high proportion of migrants or very poor populations. Similar approaches were adopted for assessment in the other countries.

The initial assessments were comparatively simple to make, being based on the statement of the village leader or the villagers themselves that a search worker had been in the area and the finding of a smallpox poster or marking on a wall (Plate 10.35). More sophisticated assessment became possible when house-to-house searches began and a reward was offered. Individual households were then asked whether they had been visited by a search worker, whether they knew the amount of the reward and whether they knew where to report cases of smallpox. Later, when workers endeavoured to detect cases of measles, chickenpox and other

WHO / P. ROBERTS

illnesses with rash, the incidence of these diseases in different areas was compared and those in which few such cases were reported were searched again by special teams.

Assessment itself involved large numbers of people. In India, for example, 3 million households in 107 000 villages were routinely visited following each search. The numbers were smaller in Somalia, but finding the scattered villages and nomad camps made the task no less challenging.

The value of assessment in the search programme suggested its possible use for other purposes; this was demonstrated in Bangladesh (Joarder et al., 1980), in which teams also evaluated the availability and utilization of tube-wells in rural areas, contraceptive pills (and public awareness of family planning methods), and rural health centres. In other areas, data regarding the occurrence of measles, tetanus, poliomyelitis and blindness were obtained.

Surveillance teams were especially important in the planning and assessment of the search programmes and in other types of search procedure. Until 1973, there had been few of them in Asia, and they had been inadequately supervised and primarily responsible to state or district authorities; from 1973 to 1975, their numbers grew rapidly, proportionately more being assigned to areas in which smallpox was endemic. Those responsible for surveillance over the largest

contacted. The cards were subsequently useful in assessing the efficacy of search among nomads.

Special search programmes were required for areas especially difficult of access. Each country had a number of such areas, usually with a small, widely dispersed population and few health services, where teams often had to travel by boat, horse or camel or to walk for one or more weeks. Where variola major had been present, as in Asia, it was possible through facial pockmark surveys to determine the recent past history of smallpox. Such surveys in Bangladesh, India, Pakistan and Nepal during 1975–1976 revealed only a few small outbreaks which had occurred earlier but not been reported (Ježek & Kanth, 1978; Nair, 1978; Basu et al., 1979; Ježek et al., 1978b; Joarder et al., 1980). This was partly because of infrequent contact between the inhabitants of these isolated areas and those of the more populated endemic areas and partly because of the traditional practice of isolating patients that was followed by many tribal peoples.

The remote areas of Ethiopia and Somalia presented a different challenge. Variola mi-

nor had been present in these areas during recent decades, rarely leaving persistent facial pockmarks. Because the disease was mild, patients were usually not isolated and smallpox persisted for long periods. Repeated searches were required to confirm the absence of smallpox, and these were conducted in many areas of both Ethiopia and Somalia as well as in the southern Sudan (WHO/SE/74.67, Bassett et al.; Foster et al., 1978; Ježek et al., 1981; Tekeste et al., 1984).

Ultimately, the most effective method of ensuring prompt reporting proved to be to offer a reward. This had first been done in Indonesia in 1972, when a large outbreak was discovered in what was thought to be a smallpox-free area of Java (see Chapter 13). Numerous illnesses with rash were reported but none proved to be smallpox. Later that year the practice was adopted in Karnataka State in India, and soon thereafter in several southern states of that country, all of which were free or virtually free of smallpox. The rewards ranged from 10 to 25 rupees (US\$1.30–3.25). The practice of offering a reward was slow to be adopted more widely, however, because many national and state

officials feared that it would establish a precedent whereby a reward would be expected for the report of any illness. This fear proved to be unfounded.

At the beginning of 1974, most Indian states sanctioned a reward of 50 rupees (US\$6.25), rising to 100 rupees (US\$12.50) at the end of 1974 and to 1000 rupees (US\$125) in July 1975, shortly after the occurrence of the last case. The offer of even larger sums was considered but programme staff believed that too large a reward would cease to be credible. Even the amounts mentioned represented scarcely believable sums in a country in which workers were sometimes paid 10 rupees or less per day. Initially, the rewards were not well publicized by the health workers, who wished to keep them themselves; but the problem was resolved by offering 2 rewards, one for the person who reported the case and the other for the health worker who investigated it. Only 2 countries besides India offered a reward while cases were still known to be occurring: Bangladesh in mid-1974 and Somalia in April 1977. In Bangladesh, 220 000 takas (US\$27 280) were paid in all, a modest sum for the improvement in reporting which occurred. The total expenditure in rewards is not known for India or Somalia, but it is believed to have been substantially less than in Bangladesh.

Rewards were also offered in other countries after they became free of smallpox but, although many suspected cases were reported, none was confirmed. Finally, in 1978, the World Health Organization offered a reward of US\$1000 for the reporting of a case that could be confirmed; this, too, brought to light a great many suspected cases with rash due to many different causes. Although none proved to be smallpox, the offer of the reward was of value in confirming that eradication had been achieved.

Many approaches were used to publicize the reward but studies showed that the most

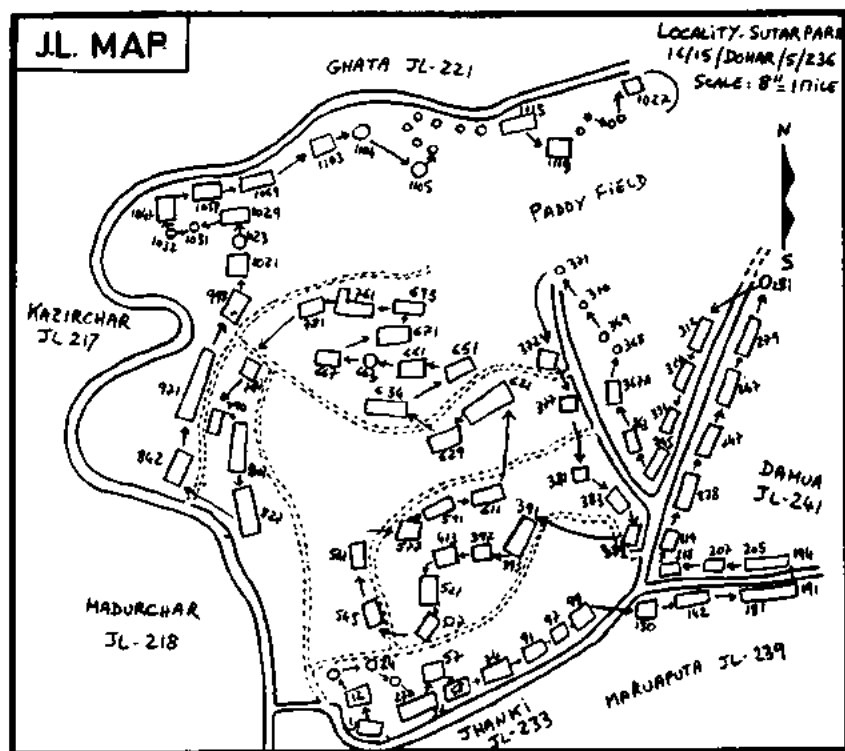

effective was simply for search workers and surveillance teams to talk to the people. In surveys in both urban and rural areas of India, 70-85% reported that they had learned about the reward from a search worker; even higher figures were recorded in Somalia.

In 1975, when smallpox incidence had decreased to very low levels, other techniques were used in case detection. Health centres and hospitals were asked to enter the names and addresses of all suspected cases in a "rumour register" so as to obtain a record of such cases which could later be checked by surveillance teams; specimens were taken in increasing numbers from patients with chickenpox in order to ensure that errors in diagnosis were not being made; and surveys were conducted over wide areas to detect persons with facial pockmarks in order to determine whether any had had smallpox after transmission had apparently been interrupted. These activities continued throughout the certification period and were among the important steps taken to certify that transmission had been interrupted (see Chapter 24).

Of the many methods used to detect cases after 1973, in India house-to-house search was clearly of the greatest importance, followed by field investigations of the cases detected (Table 10.11). In Somalia, however, reports from the public in response to the offer of the reward previously mentioned were more important, that offer having begun to be publicized in April 1977 before house-to-house searches had been organized. Because of the reward, young nomads found it profitable to search widely for cases and many reports were received from them.

#### *Containment measures after September 1973*

In the change of strategy which began in the autumn of 1973, the initial concern was to ensure the prompt and more complete

**Plate 10.38.** A sketch map of an infected village, prepared for containment activities in Bangladesh. All the houses were numbered; arrows indicated the order in which the houses were to be searched.

detection of cases. It was expected that the outbreaks could then be effectively contained by smallpox eradication staff in the conventional manner. The discovery of more than 10 000 cases in India during the first search in 1973 was unexpected and, in many areas, the numbers of outbreaks proved to be far beyond the capacity of existing staff to deal with. In heavily infected areas, help was at first sought from existing health staff but this often proved counterproductive, since those who discovered cases soon found themselves burdened with the additional task of containing the outbreaks. Accordingly, arrangements were made to ensure that those who searched were not also responsible for containment.

Because of the difficulties in developing search operations and the large numbers of cases, containment in all countries until the summer of 1974 continued to consist in little more than the isolation of the patient, a rapid survey to detect additional cases, and the vaccination of household contacts and those in some 30 surrounding households. It gradually became apparent that these measures were inadequate, since outbreaks which were thought to have been contained not

only persisted but also spread to other areas. That summer, as numbers of smallpox cases decreased substantially, it became possible in India to assess carefully the failures in containment and to develop special measures to correct them. Over the succeeding months, containment measures became increasingly stringent, making it necessary to engage many additional workers, often locally recruited and trained. Other countries subsequently adopted similar measures.

Measures were taken to ensure more complete vaccination coverage in the outbreak area, the first step being to assign responsibility for each outbreak to a team leader who was a member of the smallpox eradication programme staff. He prepared a sketch map of the affected locality (Plate 10.38) and employed a team of local health workers to paint numbers on the doors of the houses or, in the case of tents, on WHO smallpox recognition cards, which were then attached to the entry flap of each tent. All residents of the village or district of a town were listed by name and by house before containment vaccination was begun, since it was found that fewer persons were then successfully hidden in an effort to avoid

vaccination. The vaccination programme, which followed the listing, required 1-3 days, the team leader and a number of vaccinators remaining in the village for 1 or more nights so as to vaccinate those who were absent during the day. Eventually, a vaccinator remained in an infected village for 28 and, later, for 42 days following the onset of the last case in order to vaccinate visitors, ensure that the patient remained isolated and detect promptly any additional patients who had been vaccinated too late in the incubation period to be protected. In Somalia, 1 or 2

vaccinators usually travelled with each affected group of nomads throughout this period.

For areas outside an infected village but within a radius of 8-10 kilometres, other teams moved from house to house to search for cases and to vaccinate. Because of the density of the population in many of the infected areas in Asia, this sometimes meant contacting 10 000 or more persons, a process that often took 1-2 weeks.

Wherever possible, patients were isolated in their houses, but even this required special measures. To ensure isolation, 4 guards were

hired who were instructed that at least one of them must remain at the door of the house, day and night, entry being permitted through a single door, the other doors being nailed shut. They made certain that the patient remained in the house, vaccinated all visitors and brought the necessary food, water and firewood to the patient. Two at a time were expected to be on duty during each 12-hour

period so that, if one had to leave, the other would remain. They stayed until the patient's last scabs had separated and were paid for their services at that time. Supervision was simplified by telling them that if, at any time, a supervisor found the house unguarded, all would be discharged without pay and new guards hired. Eventually a special book was provided in which the guards recorded the

name of each visitor, the date and the fact that he or she had been vaccinated.

In Ethiopia and Somalia, where many people lived in tents or small huts, and in congested areas of Bangladesh, it was difficult to isolate patients in this manner. In these countries, therefore, 2 other methods were sometimes used. The first was to construct for the patient a small separate hut with kitchen and latrine facilities and to surround it by a barrier of thornbush or bamboo. The second was to isolate the patient in a specially constructed camp occupied only by smallpox patients. Special guards were used in both cases. It was often difficult to gain the agreement of Ethiopian and Somali patients to be isolated, however, because, having the mild variola minor variety, they had few symptoms and could work and move about without difficulty. Compliance increased when all patients, on recovery, were given new clothes, their old clothes then being burnt.

From early 1974 onwards in India and later in Bangladesh and Somalia, larger numbers of national and international epidemiologists were recruited to head surveillance teams, with the aim of providing at least 1 such team for the supervision of surveillance and containment in an area with no more than 25 active outbreaks, an outbreak being defined as the occurrence of 1 or more cases of smallpox in a geographical location, such as a village, district of a town or nomad encampment. When a patient moved from one village to another—to be hospitalized, for example—this was counted as 2 outbreaks, since both areas had to be kept under surveillance. Once an outbreak was identified, it was considered "active" until 28 (later 42) days after the onset of the last case of smallpox. By this time, the patient's last scabs would have separated and any contacts who were incubating infection would have developed disease.

The surveillance teams were responsible for visiting each outbreak at least weekly to ensure that the prescribed measures were being taken; when the appropriate interval had elapsed after the onset of the last case, they were also responsible for organizing a search of the area lasting 1-2 days before certifying that the outbreak could be removed from the master list of active outbreaks.

Outbreak investigation required time and patience in order to identify with accuracy

the dates of onset of all cases and the probable sources of infection of each so as to reconstruct its development. For this purpose, and to promote an understanding of the concept of the chain of transmission, a special form had been employed since 1970. As the number of epidemiologists increased and the number of outbreaks decreased, more elaborate forms began to be used.

The surveillance team was responsible for investigating the source of infection or contacts of patients if they were in villages within its area of responsibility, but if the villages concerned were outside its area, the team notified its superiors so that other teams could investigate. However, the transmission of accurate information from one area to another regarding possible sources of infection and patient contacts proved unexpectedly difficult. The names of contacts as well as those of towns and villages often had to be spelled phonetically, since informants were usually illiterate. Whether this information was transmitted by telex, messenger or telephone, there were often difficulties in locating the persons or even the villages named.

The quality of supervision provided by the teams was proportional to the number of outbreaks and, as outbreaks became fewer, ever more intensive measures were applied, with the result that smallpox incidence showed an accelerating decline from June 1974 in India, and from the spring of 1975 in Bangladesh, when a similar approach was used there.

#### *Measurement of progress*

As has been noted above, it became the practice in 1973-1974 to record and monitor the number of active outbreaks rather than the numbers of reported cases. This focused the attention of programme staff specifically on surveillance-containment activities and, as a result, several standards for use in measurement were developed, designed to appraise the effectiveness of such activities.

*The interval between the onset of an outbreak and its detection* reflected the effectiveness of case detection. It was believed that it should be possible to detect at least 75% of all outbreaks within 14 days after the onset of the first case. This proved difficult. In India, a level of 57% was achieved during 1974-1975; in Bangladesh just over 70% in 1975; and in Somalia, 60% were discovered after intensive activi-

ties began in April 1977. However, by determining why in each instance the interval was longer than that prescribed, problems in detection were identified and the necessary changes in field operations could be made.

The response of containment teams was measured by the *interval between the discovery of the outbreak and the beginning of containment activities*. Ideally, containment should have begun on the day a case was reported, but this depended on the availability of manpower and transport. In most areas, there was a rapid response. In India, containment was started in 60% of newly discovered outbreaks on the day they were discovered; in less than 10% was it delayed for 3 days. In Somalia, containment was started on the day of discovery in only 40% of outbreaks when the programme began in April 1977 but in more than 90% by August.

The effectiveness of containment measures was assessed by the *interval, in days, between the beginning of containment and the occurrence of the last case*. This indicator was closely followed in all programmes from the autumn of 1974

onwards. The standard laid down was that no case of smallpox should occur in any outbreak more than 20 days after containment had started. This interval was long enough for containment vaccination to be completed and for smallpox to develop among those who had been vaccinated too late in the incubation period to be protected. From early in 1975, all outbreaks in which cases occurred more than 20 days after the start of containment activities were investigated by a senior epidemiologist to determine the reasons for failure and to advise on corrective measures.

The effectiveness of containment varied widely from area to area but improved with time. In India, additional cases occurred after 20 days in 25–30% of outbreaks in 1974, but in only 5% during 1975. In Bangladesh, a more rigorous interval of 15 days was prescribed as the standard. From November 1974, cases occurred in 25% of outbreaks after 15 days, a proportion which gradually decreased to less than 10% by June 1975. In Ethiopia, in 1973, smallpox persisted for more than 20 days in fewer than 25% of

outbreaks and the figure remained at or below this level until transmission ceased.

## CONCLUSIONS

Smallpox had many attributes which greatly facilitated its elimination; the strategic plan for eradication was a comparatively simple and inexpensive one; and, in principle, all countries supported the concept of an eradication programme coordinated by WHO. As has been pointed out in this chapter, however, implementation of the smallpox eradication programme was neither simple nor straightforward, and its successful outcome, even as late as 1976-1977, was by no means assured. The execution of this global programme, like that of any other, was inevitably complicated by a host of natural and political problems ranging from floods, drought, famine and war to such human failings as incompetence, dishonesty and personal antagonisms. These alone gave rise to formidable difficulties. No less of a problem was that of obtaining and sustaining a commitment to the programme on the part of national governments and international agencies alike, however beneficial for all peoples the global eradication of smallpox was seen to be. In consequence, serious shortages of resources and lack of cooperation continually hampered progress. Although an understandable scepticism prevailed at first as to the feasibility of eradicating this or any disease, problems persisted even when it was clear that eradication was imminent and continued throughout the process of certification.

Nevertheless, the global eradication of smallpox was ultimately achieved, a success which can be attributed essentially to four factors. The first and most important of these was the existence of an international organization through which a collective international policy could be expressed and which could call on governments and individuals in fostering and coordinating activities directed towards a common purpose. Although the execution of the programme was sometimes less than optimum, no other agency could have obtained the requisite cooperation and international commitment and participation to achieve an objective of this magnitude.

The second important factor was the dedication and competence of a substantial cadre of both national and international staff,

many in their 30s and 40s, who continually learned from experience—adapting, innovating and creating to enhance the programme's activities. They, in turn, served to stimulate and to inspire the large number of national health staff whose potential had never been fully realized.

The third factor was that the strategic plan was stated in terms of principles and illustrative methodologies rather than of directives. Moreover, the WHO Handbook explicitly encouraged programme staff to explore alternative approaches and anticipated that changes would be made as experience was acquired. As a consequence, each national programme was different and each evolved and changed over time. In addition, experiences and observations in one area were rapidly communicated to others and then appropriately adapted and applied.

Finally, the fourth factor was the recognition in 1967 that, however much was known about smallpox and however adequate the tools for eradication appeared to be, continuing research both in the field and in the laboratory would be essential. Thus, research was actively promoted throughout the course of the programme and scientists from all parts of the world responded to WHO's requests with extraordinary generosity and commitment, commonly making their observations available long before publication. Without the contributions provided by research, the achievement of smallpox eradication would have been doubtful at best.

The programme itself developed with surprising rapidity from 1967 to 1973, employing few international staff and comparatively straightforward methods of mass vaccination and surveillance—containment. In large measure, this success, where earlier efforts had failed, can be attributed to the use of quality control in the programme, something that had been uncommon in most of the endemic countries. Testing in international laboratories ensured that vaccine was potent and stable; assessment of vaccination campaigns determined whether the proportion of vaccination takes was satisfactory and the coverage adequate; and improved reporting systems provided evidence of progress towards the ultimate objective of the programme—the absence of smallpox cases.

In 1973, when endemic smallpox was confined to 5 countries in the Indian subcontinent and eastern Africa, increasing resources became available through voluntary

contributions, permitting an intensification of work in the problem areas. Surveillance-containment programmes in the 5 countries concerned became steadily more sophisticated and activities began to be documented in greater detail. Increasing numbers of international and national staff were recruited for full-time service and printed forms for recording data increased markedly both in number and in the amount of detail they contained. Without this effort, smallpox transmission would have persisted far longer than it did, if indeed eradication could have been achieved at all, given the population density and movements of peoples in the Indian subcontinent, war in Ethiopia, and the suppression of reports of smallpox in Somalia.

Until 1973, successful national programmes required only a few international advisers in addition to their own health personnel, and a handful of simple forms. Case detection and containment programmes were simple and relied heavily on existing

health service units. This is not adequately reflected in the published literature, as most papers deal with programmes during the period 1973-1977 and suggest a pattern of activity which, although necessary then, was not characteristic of programmes in the more than 20 countries which succeeded in eradicating smallpox before 1973.

Chapters 12-22, which deal with national programmes, describe more fully the wide variety of activities carried out, the problems, the successes and the mistakes. What was apparent in all, however, was the potential for extraordinary achievement on the part of WHO and national health service staffs acting in concert, given proper guidance and appropriate support in coordination, management and the allocation of resources. The potential for success in eradicating smallpox was greater in 1967 than anyone initially believed; the potential for successfully applying measures for the control or elimination of other diseases is far greater 20 years later.

## A CHRONOLOGY OF PROGRESS, 1967-1980

### Introduction

This section presents a year-by-year summary of progress in smallpox eradication (Fig. 10.4) to provide a frame of reference for the chapters describing the eradication programmes in individual countries or groups of countries (Chapters 12-23) and the certification of eradication (Chapters 24-27).

In compiling the data on the incidence of smallpox over the years, we have reviewed the available and sometimes conflicting reports and have made use of the figures that in our opinion most accurately reflect the situation at the relevant time. Some figures differ from those previously published and from those in the official national and international records. The differences are greatest for the early years of the programme, when notifications of reported cases were most delayed and incomplete. The reader who wishes to refer to the contemporaneous figures may consult the *Weekly epidemiological record*, which provided a compilation of the most recent information every 2-3 weeks and a summary of the status of the programme as a whole twice a year.

Throughout the course of the Intensified Smallpox Eradication Programme, particular importance was attached to defining which countries had endemic smallpox and which did not. Although this might seem a straightforward task, it was not so, especially during the first few years and for the smaller countries. The first summary of the situation in this period was provided in a report by the Director-General of WHO to the forty-first session of the Executive Board, which met in January 1968. In that report, 29 countries or territories were identified as being "endemic" (30 if East Pakistan, which later became Bangladesh, and West Pakistan are considered separately). Later information led to Cameroon, Southern Rhodesia and Yemen being added to the list; each had reported only a few cases in 1967 and these were at first assumed to represent importations, but they were not. However, 2 small countries—Lesotho and Swaziland—were mistakenly shown as having endemic smallpox in 1967 because of their proximity to infected areas in South Africa and their rudimentary reporting systems. Subsequent information suggests that both were smallpox-free. In later years, other countries were mistakenly identified as non-endemic because of government suppression

of smallpox notifications. This occurred for Iran from 1970 to 1972, for Iraq from 1971 to 1972 and for Somalia in 1976. Later information received from government and other sources served to clarify the situation.

### The Situation at the Start of the Intensified Programme, 1967

The first year of the Intensified Smallpox Eradication Programme saw a substantial acceleration of activities compared with previous years. This was primarily the consequence of greater financial resources and more staff becoming available from WHO and of the implementation of the regional programme in western and central Africa that received direct support from the USA. Certainly this enhanced effort started none too soon, for the number of reported cases of smallpox in the world rose in 1967 to 131 776, one of the highest totals for a decade. Little of this increase can be attributed to better reporting since few countries had yet improved their case-notification procedures. Indeed, it soon became evident that reporting was even less complete than had been feared; it had been thought that perhaps 1 case in 20 was being notified, but experience in the field began to indicate that a figure of 1 in 100 was probably nearer the mark.

The 31 countries or territories classified as having endemic smallpox (see box) were in 4 epidemiological zones sufficiently separate to make it unlikely that if one was freed from smallpox, it would become reinfected from another. These were: (1) Brazil, (2) Indonesia, (3) Africa south of the Sahara, and (4) a contiguous group of southern Asian countries extending from Afghanistan through West Pakistan, India and Nepal to East Pakistan. The eastern borders of East Pakistan and India were taken as the eastern limit of endemic smallpox on the Asian mainland, although Burma had imported cases from 1967 to 1969. The People's Republic of China was not in relations with WHO in 1967 and provided no official information, but reports by visitors suggested that smallpox was not present there; the government confirmed this in 1973.

### Programme implementation

Basic strategies and principles were issued in July in a WHO *Handbook for Smallpox Eradication in Endemic Areas*, and these were endorsed in September by the WHO Scientific

fic Group on Smallpox Eradication. Surveillance reports giving epidemiological information and documenting progress in the countries were widely distributed by WHO from September on.

WHO gave priority to the eradication programmes in the smaller of the major epidemiological zones—Brazil and Indonesia—in the expectation that success there would free resources that could be concentrated on the larger and probably more difficult zones. Brazil's programme had started in 1966, and Indonesia and WHO agreed in December 1967 on one to start in 1968. Eradication programmes began or were under way in 12 of the other 29 endemic countries at the end of 1967. Programmes in Cameroon, Dahomey, Ghana, Mali, Niger, Nigeria, Togo and Upper Volta were included in the regional western and central Africa programme supported by the USA; a programme in the Democratic Republic of the Congo started late in the year; and WHO-supported programmes were continuing in Afghanistan, Nepal and Zambia, although only the last of these represented a meaningful effort.

Many other countries decided to undertake programmes and developed plans of operations with advice from WHO; the procurement of supplies began as each plan was finalized. In India, however, a serious problem was posed by the government's decision in December 1966 to terminate its 5-year-old vaccination campaign. That country was then reporting more than one-third of the world's cases. Appealed to by WHO, it agreed that a joint India-WHO team should undertake a field assessment of the situation late in 1967 and develop an alternative plan.

#### *Other developments*

In May the first annual meeting of WHO regional and Headquarters officers responsible for smallpox eradication was held to discuss and agree upon plans, needs and priorities. In December there was held in Thailand the first of many intercountry meetings at which the staff of programmes in different countries and their WHO counterparts exchanged experiences and debated strategies.

The supply of potent, stable vaccine being crucial to success, arrangements were made for laboratories in Canada and the Netherlands to test vaccines and to help countries to develop their own production. At the same time, WHO initiated a survey of the vaccine quality and production capacity of laboratories throughout the world. More than 200 batches of vaccine were tested under WHO's auspices in 1967 (43 batches in 1966, 12 in 1965). All countries were asked to contribute vaccine and by the end of the year 15 million doses had been distributed by WHO, 4 times as many as in 1966. Over and above this, the USSR provided more than 75 million doses, mainly to Afghanistan, India and Burma, and the USA about 25 million doses for use in Africa.

After trying and rejecting several cheaper variants of the jet injector, which had come into operational use in 1967, WHO assessed the capability of the bifurcated needle—a new device by which a very small amount of vaccine could be introduced almost painlessly into the skin by multiple punctures. By the end of the year it had proved to be the instrument of choice.

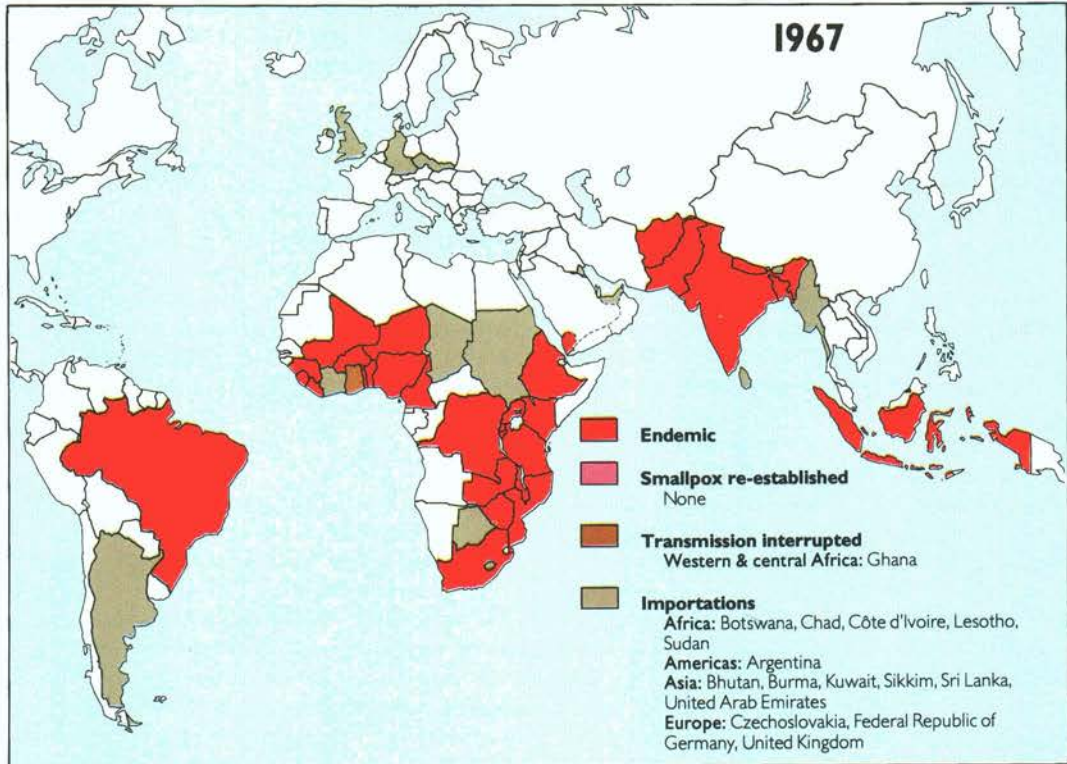

#### **Countries or Territories with Endemic Smallpox in January 1967**

*Africa, eastern and southern:* Burundi, Democratic Republic of the Congo (Zaire from 1971), Ethiopia, Kenya, Malawi, Mozambique, Rwanda, South Africa, Southern Rhodesia (Zimbabwe from 1980), Uganda, United Republic of Tanzania, Zambia.

*Africa, western and central:* Cameroon, Dahomey (Benin from 1975), Ghana, Guinea, Liberia, Mali, Niger, Nigeria, Sierra Leone, Togo, Upper Volta (Burkina Faso from 1984).

*Americas:* Brazil.

*Asia:* Afghanistan, East Pakistan (Bangladesh from 1971) India, Indonesia, Nepal, Pakistan (West Pakistan until 1971), Yemen.

**Plate 10.42.** Smallpox in the world, 1967: endemicity in 31 countries or territories.

### The Situation in 1968

During the second year of the Intensified Programme, the number of endemic countries with special eradication programmes increased from 12 to 19, and agreements were reached or appeared imminent for the commencement of programmes in 8 others. However, 4 remained as problems—Southern Rhodesia, South Africa, Mozambique and Ethiopia. The first two, with which WHO had no official contact, caused little immediate concern as they reported few cases and had a reasonably extensive health infrastructure. However, civil war in Mozambique precluded an extensive programme there, and Ethiopia declined to initiate a programme.

The number of countries with endemic smallpox in 1968 remained at 31, transmission having stopped in Ghana in 1967 but Sudan becoming infected following importations from Ethiopia. The number of reported cases diminished from 131 776 to 79 951 but this was almost entirely accounted for by a decrease in India (from 84 902 to 35 179 cases). Whether this represented better smallpox control in India or simply a longer-term cyclical trend in the incidence was unknown.

#### *Africa*

The most heartening progress was made in the regional programme in western and central Africa, which included some of the world's poorest and most heavily infected countries. By the end of 1968, 62 million persons had been vaccinated—almost 60% of the total population; in September special surveillance-containment programmes began in many of the countries. There was a sharp drop in the number of cases reported and 6 of the 10 remaining endemic countries interrupted transmission. However, civil war in Nigeria, the most populous country, threatened to extend throughout the country. In eastern and southern Africa, Uganda and Zambia also stopped transmission.

#### *South America*

Brazil, the only endemic country in the Americas, made notable progress in its vaccination campaign and, by the end of the year, was vaccinating 1.3 million persons each month. There was little improvement, however, in the notifications or the surveillance programme. Neighbouring countries in

South America also conducted vaccination campaigns but cases—all due to importations from Brazil—were detected only in French Guiana and Uruguay.

#### *Asia*

The programme in Indonesia began in 1968 and within 6 months transmission was interrupted throughout East Java, a province with more than 25 million persons. Although special vaccination campaigns were begun or intensified throughout Indonesia and other endemic Asian countries, progress was generally poor and reporting was little improved.

#### *Other developments*

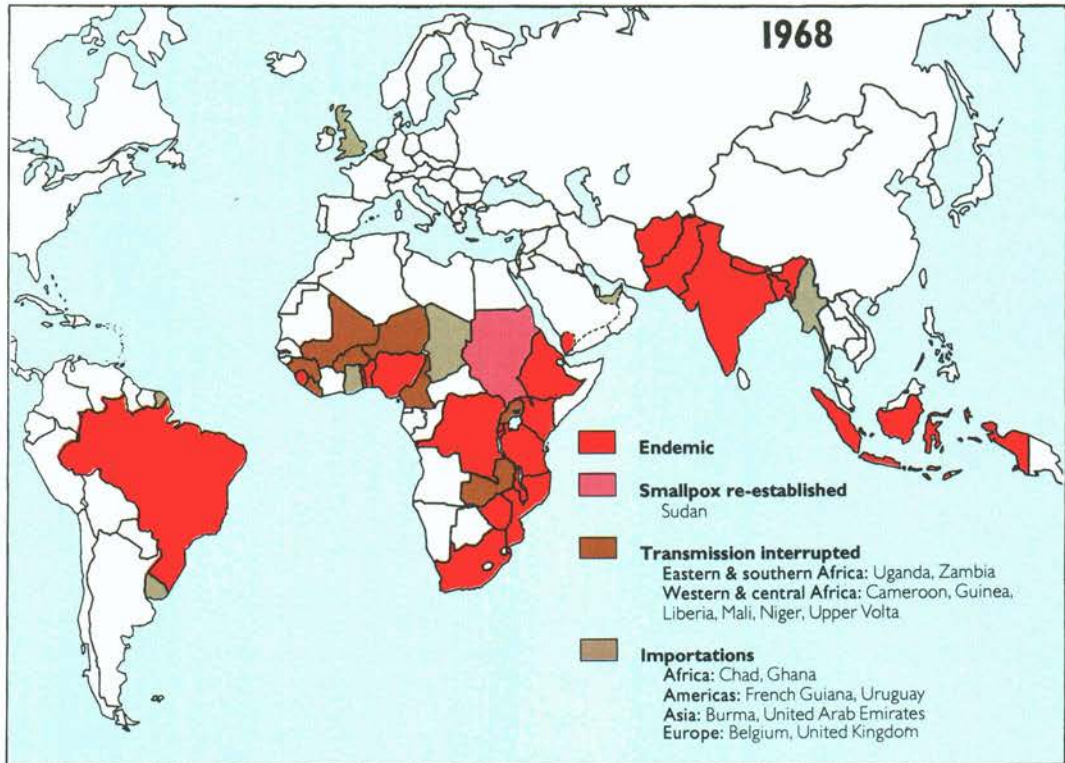

The lack of attention to surveillance was a matter of special concern and surveillance was stressed as being "as important as the vaccination programme itself" at the Twenty-first World Health Assembly in May and emphasized again at an intercountry seminar in Kinshasa in November. Special training materials were developed to foster an understanding of the principles and methods involved.

The bifurcated needles, introduced for general use, alleviated some shortages of vaccine, but it became apparent that the endemic countries would soon need to produce much more vaccine. WHO convened experts in vaccine production to develop a manual on production methodology, and the Organization sent consultants to 24 laboratories and provided equipment and reagents to 30.

The dissemination of information about the programme and about field observations was facilitated as reports about the programme began to be published every 2-3 weeks in the *Weekly epidemiological record* from May onwards and other documents were distributed regularly to senior eradication staff throughout the world.

Activities during the first 2 years of the Intensified Programme laid a sound foundation but how this could be built upon in the field was uncertain. Although the progress in western and central Africa was encouraging, the resources made available there by the USA were greater than could then be foreseen for other countries; progress elsewhere was made primarily in the countries with the more advanced health services. At the end of 1968, the feasibility of global smallpox eradication was by no means certain.

**Plate 10.43.** Smallpox in the world, 1968.

### The Situation in 1969

Certain evidence of progress came during the third year of the Intensified Programme. Only 23 countries recorded endemic cases that year—8 fewer than in 1968—and in 5 of them transmission was interrupted. Thus, during a period of only 3 years, 15 countries successfully eliminated smallpox. Except for Yemen, they were all in Africa, and 10 of them were in western and central Africa where, at the end of 1969, smallpox persisted only in northern Nigeria. Kenya and Mozambique also ceased to report cases but because surveillance was inadequate there, the absence of cases was viewed with scepticism at first.

Although improved notification procedures led to more complete reporting in several countries, the total number of cases reported in the world declined to 54 199, the lowest figure that had ever been recorded. The optimism this gave rise to was tempered, however, by the realization that none of the countries in which transmission had been stopped was large, only Kenya having a population of as many as 10 million persons.

#### *Africa*

The successes in Africa were encouraging but 4 of the largest countries still presented serious problems. The programme in the Democratic Republic of the Congo progressed well but the country was one of the largest in Africa, transport presented formidable problems and smallpox was prevalent everywhere. In the Sudan, smallpox spread widely after being imported and civil war throughout its southern provinces made activities impossible there. In November, Ethiopia, which presented the greatest logistic challenge, reluctantly agreed to a programme but it could not begin until 1971. About South Africa, little was then known except that the number of reported smallpox cases increased from 43 in 1967 to 246 in 1969.

#### *South America*

Brazil intensified its vaccination campaign and began surveillance programmes in 4 states. Because of this, notifications improved and the number of reported cases increased from 4372 in 1968 to 7407 cases in 1969. Near the end of the year, however, the principal surveillance officers were discharged and the director of the programme resigned.

#### *Asia*

The programmes in Afghanistan, Indonesia and Nepal were substantially strengthened during 1969 but there was little progress to report in either India or Pakistan. Mass vaccination campaigns in East and West Pakistan were far behind schedule and surveillance activities were nominal, at best. India postponed the signing of an agreement to strengthen its programme and, in 1969, reported more births than primary vaccinations. India's decision that year to begin using the bifurcated needle and to terminate the use of liquid vaccine was almost the only encouraging news from a country which each year continued to report one-third to one-half or more of the world's cases of smallpox.

#### *Other developments*

Vaccine production increased in a number of the endemic countries in 1969, but shortages could be foreseen as the year progressed and more programmes began. Despite appeals for additional donations of vaccine, the quantities contributed in 1969 were smaller than in 1968.

The attainment of global eradication rested on the premise that there was no animal or other natural reservoir of the virus, but firmer evidence of this was required. In March 1969, the first of a series of biennial meetings of an informal group of research workers was convened by WHO in Moscow to plan and implement a collaborative research programme to discover whether any reservoir of variola virus existed and to elucidate the behaviour of the closely related monkeypox virus.

The promotion of surveillance-containment activities continued to meet with limited success and so the Director-General presented a special report to the WHO Executive Board which recommended for every country the "immediate investigation of every reported case of smallpox by trained investigators, the tracing of the source of infection and the prompt application of containment measures". In May, a seminar for the countries of western and central Africa provided important documentation of this approach, and another, held in Pakistan in November, for participants from 11 countries of the Eastern Mediterranean and South-East Asia Regions, stressed its importance. Translation of the methods into practice, however, continued to progress slowly.

Plate 10.44. Smallpox in the world, 1969.

### The Situation in 1970

Developments in 1970 gave grounds for genuine optimism that global smallpox eradication could be achieved: only 18 countries recorded endemic cases during the year and in 6 of these transmission was interrupted—5 in Africa and 1 in Asia. Large populations were involved. With the containment of the last cases in Nigeria in May, more than 100 million persons in western and central Africa were in a smallpox-free region. Wholly unexpected was the elimination of smallpox from the densely populated area of East Pakistan (population in 1970, almost 66 million) following a brief but effective surveillance-containment programme. The reported cases of smallpox in the world during 1970 numbered only 33 693, a decrease of 38% from the record low of the previous year.

#### *Africa*

At the end of 1970, smallpox was considered to be endemic in only 5 countries in the whole of Africa: the Democratic Republic of the Congo, Ethiopia, Malawi, South Africa and the Sudan. Excellent progress was made in the Democratic Republic of the Congo during the year and South Africa embarked on a special vaccination campaign. Sudan's programme, however, progressed slowly in the accessible areas and nothing could yet be done in the strife-ridden southern provinces. Ethiopia's programme had not yet started, and the epidemiological situation in Malawi was unclear.

#### *South America*

The increased incidence of smallpox reported during 1969 had brought additional resources and support to Brazil's programme; its vaccination campaign accelerated and by the end of 1970 it appeared to be on the verge of interrupting transmission. Programmes in other countries were proceeding adequately and only 1 outbreak was detected, in an Argentinian town on the Brazilian border.

#### *Asia*

Indonesia conducted a successful surveillance-containment programme and estimated that by the end of the year 85% of its population resided in smallpox-free areas. Although transmission had been interrupted

in East Pakistan and programmes in Afghanistan and Nepal were progressing well, those in India and West Pakistan were not. In West Pakistan, a poorly conducted mass vaccination campaign lagged far behind schedule. India agreed to strengthen its national structure with WHO assistance, but otherwise remained confident as the number of reported cases continued to decrease, only 12 773 cases being reported in 1970 compared with 84 902 cases in 1967. Late in the year, however, it became evident that this was partly an artificial decrease, changes in the national notification system serving to inhibit reporting.

To encourage surveillance-containment activities in Asia, a seminar was held in New Delhi in December 1970 for countries throughout the South-East Asia Region. West African and Indonesian staff described their successes with this strategy but few changes followed.

A significant event, although it was not recognized until a year later, was the reintroduction of endemic smallpox into Iran. Major epidemics were to follow, with spread of the disease to neighbouring countries and eventually to Europe.

#### *Other developments*

With more eradication programmes in progress, increasing resources were required. Efforts to obtain additional donations met with little success, and an attempt to have WHO funds that were available in the Americas reallocated for use in Asian countries also failed. Vaccine was short throughout 1970 and donated vaccine frequently had to be dispatched on the very day it was received in Geneva. Towards the end of the year, it became apparent that it would be far more difficult to eradicate smallpox from the remaining endemic countries than it had been in those which had already been freed of the disease.

Another unexpected problem occurred when, in the second half of the year, human cases of monkeypox, clinically indistinguishable from smallpox, were discovered in Liberia, Sierra Leone and Zaire. Although monkeypox was not caused by the variola virus, the question arose whether it might behave like smallpox and be sustained by human-to-human spread. Extensive field and laboratory investigations began immediately but not until the late 1970s could the fears be fully allayed.

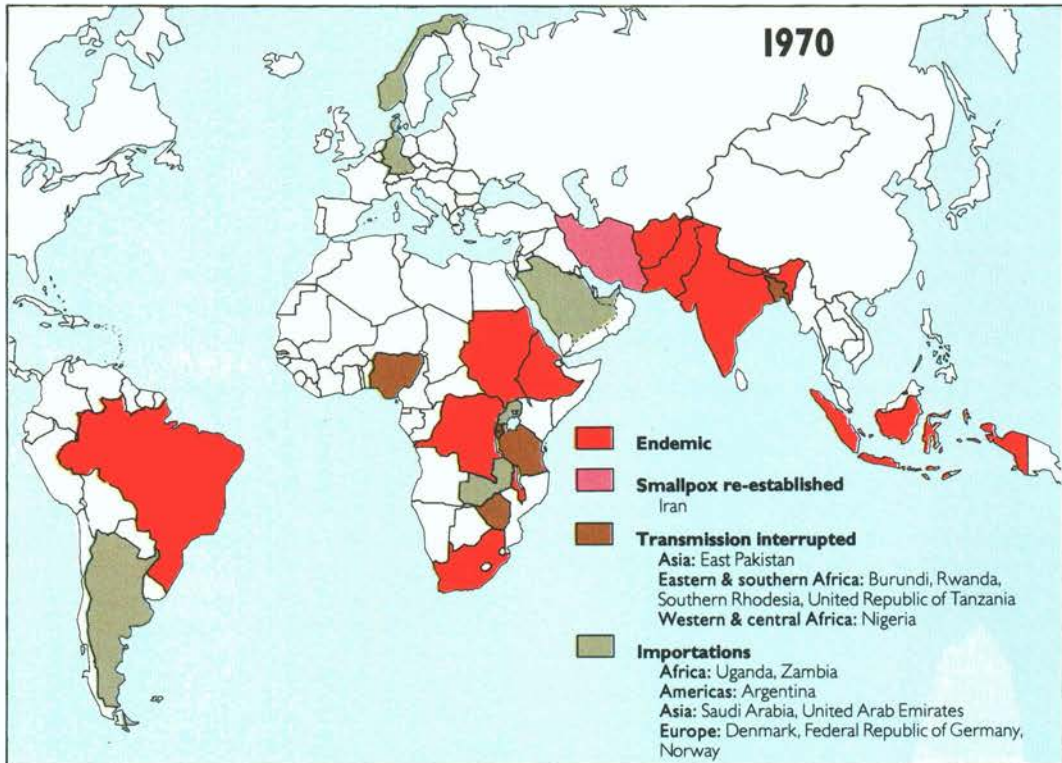

Plate 10.45. Smallpox in the world, 1970.

### The Situation in 1971

The fifth and sixth years of the Intensified Programme, 1971 and 1972, were years of transition between the remarkably successful period 1967-1970—when smallpox was successfully eliminated from large areas of the world with few resources—and the succeeding years, 1973-1977, when ever larger resources and more heroic measures were required to stop transmission in the few remaining endemic countries. In some parts of the world remarkable progress was made during 1971, but in others there were setbacks and portents of future problems. The year 1971 began with endemic smallpox in 12 countries, 4 of which interrupted transmission during the year, but 2 others became reinfected—Botswana and Iraq. For the first year since the programme began, the number of reported cases increased, from 33 693 in 1970 to 52 807 in 1971.

#### *Americas*

In April, the last cases in Brazil, and in the Western Hemisphere, were detected. Thus, the first of the 4 major epidemiological zones became smallpox-free. A plan of work was immediately developed for investigations and reports that would permit the certification of eradication after 2 years.

#### *Africa*

After transmission had been interrupted during the year in Malawi, South Africa and Zaire (formerly the Democratic Republic of the Congo), smallpox was endemic in only 3 African countries at the end of 1971—Ethiopia, the Sudan and Botswana (where it spread widely after having been reintroduced just as the last cases were occurring in South Africa). The programme that started in Ethiopia in 1971 found smallpox to be a far greater problem than had been expected. A staff of fewer than 80 persons detected 26 329 cases, compared with the 722 cases reported in 1970. In the Sudan, smallpox continued unabated in the southern provinces affected by civil war. It was apparent that eradication throughout Africa would need a greatly intensified effort, accompanied by a measure of good fortune, to surmount the problems of civil war.

#### *Asia*

In Asia, too, both successes and setbacks occurred. The programmes in Afghanistan, Indonesia and Nepal progressed so satisfactorily

that, by the end of the year, each appeared to be on the verge of eliminating smallpox. One western state of India (Gujarat), which had been reporting 10% of the world's cases, mounted a highly effective surveillance-containment programme and succeeded in stopping transmission within a year. Epidemic smallpox, however, erupted in adjacent Indian states and, there, satisfactory programmes were slow to begin. During 1971, civil war in smallpox-free East Pakistan (which became Bangladesh in December) caused some 10 million refugees to flee to India, where most of them were housed in special camps in areas in which smallpox was prevalent. Although all persons were supposed to be vaccinated on arrival, this precaution was not taken in several camps, including one of the largest. There, smallpox broke out at the end of the year and spread throughout the camp. In West Pakistan, an unsatisfactory programme was further compromised when the country was divided into 4 largely autonomous provinces and separate programmes had to be re-established in each.

It was in the course of 1971 that the presence of smallpox in Iran first became known through numerous unofficial reports, and the government eventually acknowledged that 29 cases had occurred, all of which were said to have been importations. Much later, it was learned that smallpox had in fact been introduced from Afghanistan in October 1970 and that hundreds of cases had occurred in 1971. Subsequently, it was discovered that the disease had also spread to Iraq in November 1971.

#### *Other developments*

Sufficient progress had been made in eradication to cause the authorities in both the United Kingdom and the USA to cease their programmes of routine vaccination in 1971. However, a WHO Expert Committee on Smallpox Eradication, convened in November, presciently observed that "an effort at least equal to that made in the past 5 years" would be required to interrupt transmission in the remaining endemic areas. Although few countries were now involved, they posed difficult problems. To encourage national governments and their smallpox personnel, the WHO Headquarters staff began to spend an increasing amount of time in the field, but additional resources were not forthcoming and vaccine remained in critically short supply.

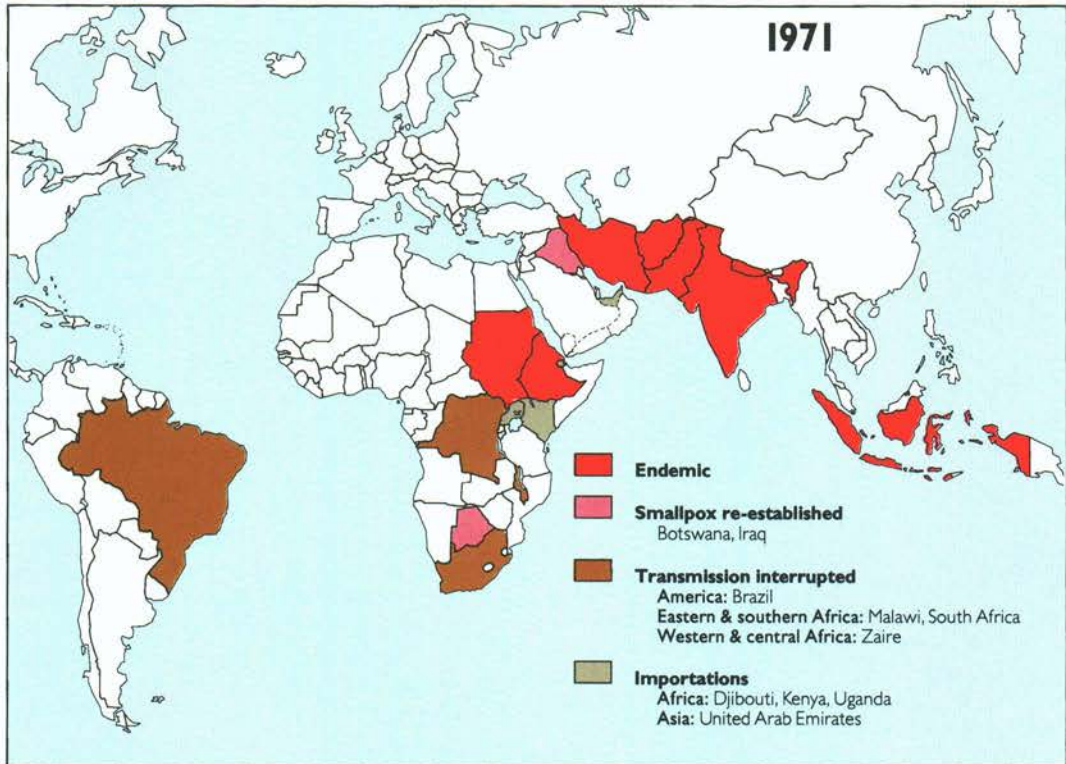

Plate 10.46. Smallpox in the world, 1971: eradication from Brazil.

### The Situation in 1972

Like the preceding year, 1972 was marked by notable successes and unexpected setbacks. Overall, the progress was encouraging. There were 10 endemic countries as the year began, but transmission was stopped in 5 of them in the course of the year. Successes in 3 of these—Afghanistan, Indonesia and the Sudan—represented exceptional achievements. The other 2 were Iran and Iraq, for which the true situation was not known with certainty until a year later. The number of cases of smallpox recorded in the world as a whole increased for the second successive year—65 140 cases in 1972 compared with 52 807 cases in 1971—but reporting was more complete and, by the summer, surveillance programmes of some sort were in place for the first time in all countries.

During the first quarter of the year, however, 3 serious problems emerged. In February, epidemics of smallpox began to spread across the newly independent country of Bangladesh as refugees returning from camps in India brought the infection with them. In March, Iraq and the Syrian Arab Republic officially acknowledged the presence of smallpox and soon thereafter a major outbreak occurred in Yugoslavia, imported from Iraq. Finally, in April, a WHO epidemiologist, on arrival in Botswana, confirmed that smallpox had already spread widely there.

Despite these problems, the geographical extent of the infected areas continued to diminish and it was proposed that "the final phase" should begin in September, the objective being a nil incidence by June 1974. Intercountry seminars were held in Ethiopia (September), India (November) and Pakistan (November) to launch this special effort, referred to for the first time as "Target Zero" in an issue of the WHO magazine *World health* and in the first of a series of fortnightly reports circulated by the WHO Smallpox Eradication unit.

#### *Africa*

The progress in 1972 in the 3 endemic African countries exceeded expectations. In the Sudan, the civil war in the southern provinces ceased and an effective surveillance-containment programme succeeded in interrupting transmission in December, more than a year earlier than WHO staff had expected. Botswana rapidly mobilized its resources and by the end of the year the interruption of transmission seemed immi-

nent. As Ethiopia's programme gained momentum, the number of reported cases decreased by 35%, from 26 329 in 1971 to 16 999.

#### *Asia*

The second of the world's major epidemiological zones became free of smallpox in January, when transmission ceased in Indonesia. This was achieved in less than 4 years and with only a modest amount of international assistance. Afghanistan, where formidable geographical and cultural problems were compounded by the practice of variolation, had once been thought the country in which attempts to eradicate smallpox were the least likely to succeed. Yet it recorded its last endemic cases in October. These successes provided some much-needed encouragement to the other endemic countries of Asia, whose situation was very different. Emergency assistance had been promptly provided to Bangladesh to stem the epidemic of imported cases but, in the post-war chaos, the health services were unable to cope. More than 10 000 cases were recorded, but it is estimated from later studies that more than 100 000 cases occurred. During the autumn, major epidemics began along the densely populated Indo-Gangetic plain in southern Pakistan, India and central and western Bangladesh. Because of the very large numbers of health staff in the Asian countries and the greater interest in eradication taken by the national authorities, hope remained high that the problems might yet be surmounted, but far more serious difficulties were to develop.

#### *Other developments*

An epidemic in Yugoslavia, the first in that country for 41 years and one of the largest in Europe since the Second World War, reminded donor countries of the severity of the disease and emphasized the importance of global smallpox eradication. Increased donations of vaccine were received and the debate at the Twenty-fifth World Health Assembly was the most extensive ever, praise for the achievements being mingled with expressions of concern about setbacks in Bangladesh, Botswana and western Asia. Despite the sentiments expressed, however, voluntary financial contributions remained at much the same level as before and WHO even decreased its regular budget allocation for the programme for the following year.

**Plate 10.47.** Smallpox in the world, 1972: eradication from Indonesia.

### The Situation in 1973

The year 1973 marked the beginning of a greatly intensified effort, which steadily increased in tempo from the autumn. As the year began, only 6 endemic countries remained. Among these, Botswana recorded only 27 cases before successfully stopping transmission in November and Nepal reported 277 cases, almost all of which could be shown to have occurred following importations from India. Although the other 4 countries (Bangladesh, Ethiopia, India and Pakistan) reported large numbers of cases, large areas within each of them were free of smallpox or nearly so. It was calculated that 90% of all cases in 1973 occurred over only 10% of the land area of the 4 countries.

#### *Asia*

During the first 6 months of the year, the number of cases reported in Asia rose sharply. Although some of this increase was thought to represent more complete notification of cases, surveillance was still by no means fully satisfactory anywhere and epidemics were being discovered of a size not seen since the beginning of the Intensified Programme. By the end of June, almost 83 000 cases had been reported, including some 49 000 in India, 27 000 in Bangladesh and 6000 in Pakistan—totals which were all higher than during the comparable period in 1972.

For these countries, it appeared that a different strategy would be required to eliminate smallpox. The comparatively simple measures for case detection and containment which had previously been effective in Africa were proving inadequate in Asia. The solution proposed was to detect cases more promptly so that they could be contained before further spread occurred. In July, therefore, Indian and WHO staff decided to mobilize all health staff in India to undertake 1-week, village-by-village searches in October, November and December in the 4 states which were then reporting 93% of all cases. In other Indian states 1 or 2 searches would be conducted during this 3-month period. A similar effort was decided upon in Pakistan. The hope was to eliminate most smallpox foci during the autumn, when smallpox spread slowly, and thus to prevent widespread dissemination during the period of rapid transmission from January to April. If this was successful, it was believed that

smallpox could be eliminated during the summer of 1974. In Bangladesh, many additional surveillance teams were provided to search for smallpox in schools and markets.

The results were encouraging in Bangladesh and Pakistan, each country reporting an incidence similar to that of the year before despite much more intensive surveillance. In India, however, more than 30 000 cases were discovered between October and December, almost 5 times as many as had been found during the same period in 1972 and, indeed, more cases than had been reported in the whole country during any of the 4 preceding years. The numbers were scarcely believable but the eradication programme staff continued to be optimistic because of the commitment of government officials, the extent of activity and the interest of the health staffs.

#### *Africa*

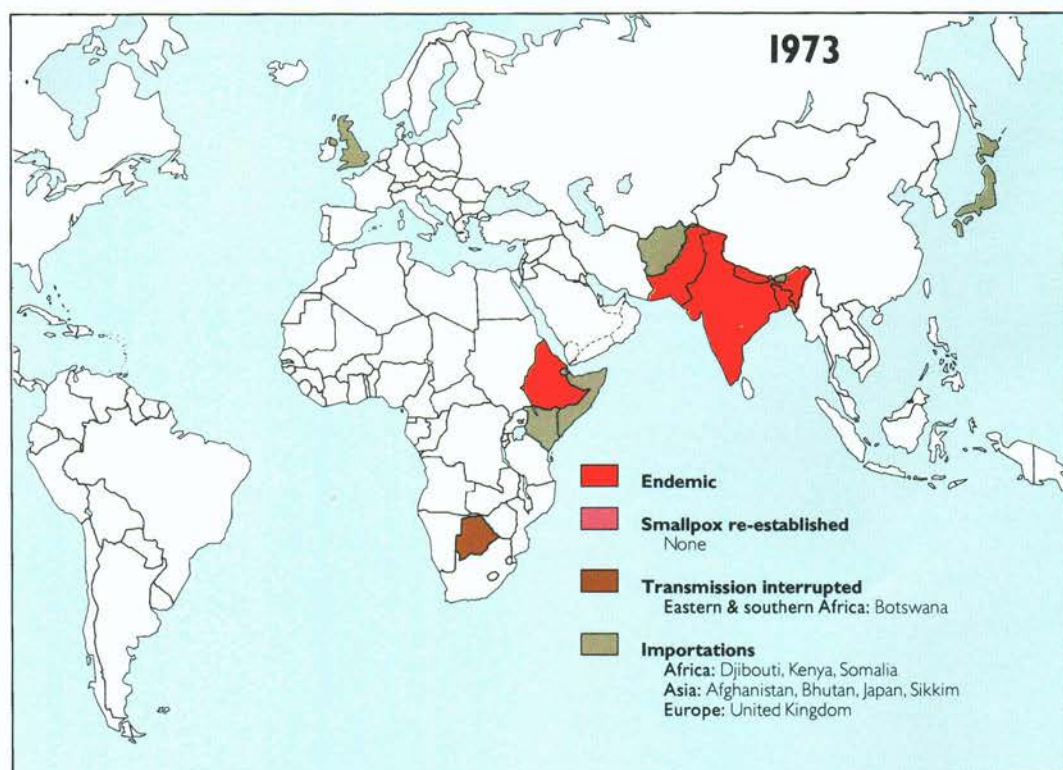

Ethiopia remained the only endemic country in Africa and there, as in Asia, more intensive measures were taken through the addition of staff and the provision of helicopters to help cope with the rugged terrain. The number of reported cases continued to decline despite more complete notifications but logistic difficulties were increasingly exacerbated by mounting civil unrest.

#### *Other developments*

During 1973, the first of the international commissions for the certification of eradication examined the programmes in the Americas and confirmed that smallpox had been eradicated from the Western Hemisphere.

A new concern emerged, however, about a possible natural reservoir of smallpox. This arose from the isolation—from monkey kidney tissue cell cultures in the Netherlands and from animal specimens collected near monkeypox cases in Zaire—of what were termed "whitepox" viruses, which were indistinguishable from smallpox virus. The WHO informal research group held its third biennial meeting in 1973 and developed a new agenda of work, but not for several years was this concern finally laid to rest and the "whitepox" viruses shown to be inadvertent laboratory contaminants.

During 1973, the number of recorded cases in the world—135 904—was the highest for 15 years, but the ultimate goal, "Target Zero", appeared none the less to be just over the horizon.

**Plate 10.48.** Smallpox in the world, 1973.

### The Situation in 1974

Throughout 1974, the programme as a whole steadily grew in intensity and accelerated in tempo. Successes in the 1973 autumn campaigns had encouraged the belief that a concerted effort of no more than 6-12 months would see the realization of global smallpox eradication. Additional national and international personnel as well as increased quantities of supplies and equipment supported this effort. It was concentrated on the shrinking endemic areas which in aggregate were smaller than the land area of Pakistan, one of the 5 countries concerned. With eradication apparently imminent, programme staff worked feverishly, driven partly by the fear that unanticipated natural or man-made catastrophes might thwart the achievement just short of the goal. Indeed, this concern proved well founded in 4 of the 5 countries.

#### *Asia*

In India, during the first 3 months of the year, intensified search programmes resulted in much more complete reporting but no more cases than in 1973. In May, however, explosive epidemics began, nearly 50 000 cases being detected that month and the worst affected state (Bihar) reporting more than 8000 cases in a week. Work was severely hampered by petrol shortages as well as by strikes which immobilized rail and air transport. Bihar State was further affected by devastating floods in the north, severe drought in the south, and civil disorder. These difficulties were compounded by a major epidemic in an urban industrial centre which resulted in the spread of smallpox to hundreds of distant villages in India and Nepal.

In Pakistan and Bangladesh, other problems occurred. Surveillance in Pakistan's largest province (Punjab) was suspended prematurely by over-optimistic provincial health authorities and an undetected epidemic in its capital, Lahore, quickly spread throughout the province. Bangladesh decided to restructure the health care system, resulting in the suspension of most activities, including those for smallpox, for many weeks. In the summer, monsoon rains brought the worst floods for many years to northern Bangladesh, displacing tens of thousands of persons.

During the first 6 months of 1974, more cases were recorded in Asia than had been reported annually throughout the world for

more than 15 years. By June, however, greatly expanded and better organized programmes were functioning and progress began to be measured in terms of the numbers of existing outbreaks (villages or town areas in which 1 case or more had occurred in the preceding 4 weeks). Asia had 8086 outbreaks in June.

Throughout the hot summer monsoon period, all staff were urged to maintain the pace of their work in order to take the fullest advantage of the seasonal decline in incidence. The effort proved successful. Pakistan detected its last case in November, and by the end of the year there were only 517 known outbreaks in all of Asia.

There was optimism that transmission would be interrupted by the summer of 1975. The only doubtful areas were those in which refugees were crowded in Bangladesh. The number of outbreaks in that country, which had been only 78 at the end of October, had tripled by the end of December. More than half, however, consisted of only 1 or 2 cases and hope persisted that, with the planned addition of health staff and temporary workers, the problem could be managed.

#### *Africa*

As more support became available, the programme in Ethiopia made steady progress in many areas of the country. The number of reported cases decreased from 5414 in 1973 to 4439 despite more complete notifications; in December, only 166 cases were discovered. In increasingly large areas of the country, however, field operations were severely hampered by the revolution that led to the deposition of the Emperor, by hostilities with Somalia in the Ogaden desert, and by the insurrection in Eritrea.

#### *Other developments*

The eradication of smallpox from Indonesia was certified by an international commission in April, but certification elsewhere was deferred pending further progress in Africa and Asia. Increasing efforts were made to recruit suitable international staff and consultants for the intensified campaign and to obtain sufficient contributions of vaccine and funds to permit the work to be sustained. At the end of the year WHO, for the first time, convened a meeting of potential donors to request contributions of US\$3.3 million, but only US\$2.1 million were pledged.

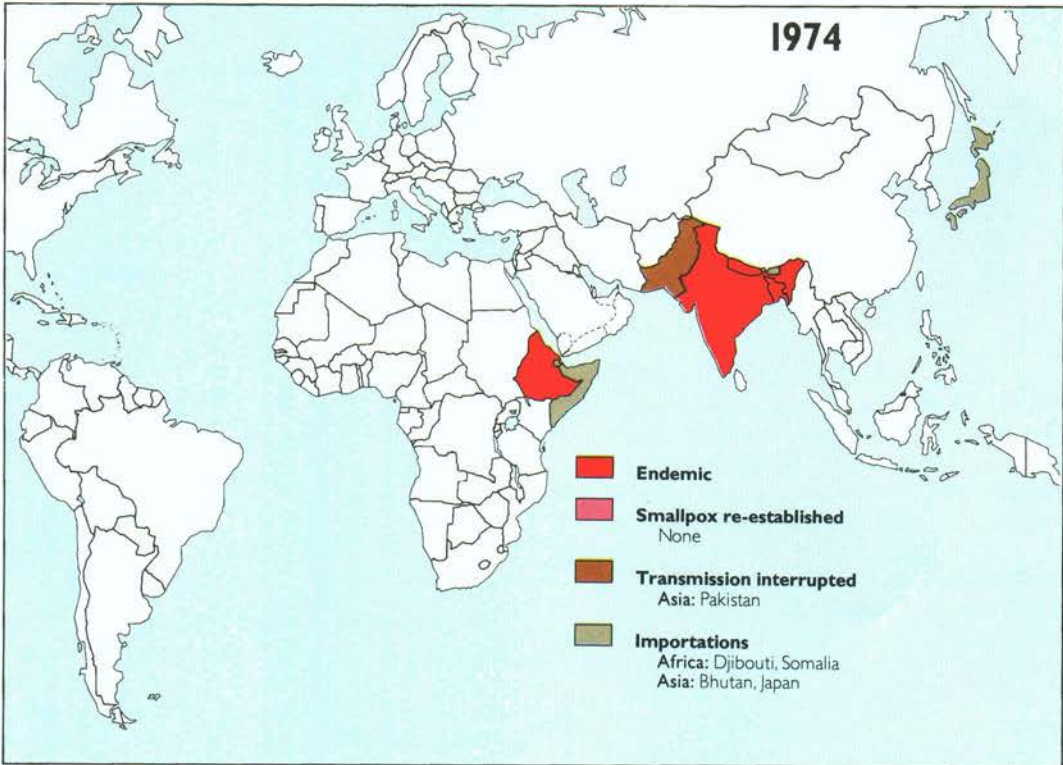

Plate 10.49. Smallpox in the world, 1974.

### The Situation in 1975

In 1975, the eradication of smallpox from Asia was achieved and, with it, the end of transmission of variola major virus, which caused the most severe form of smallpox. By the end of the year, endemic smallpox persisted only in Ethiopia, which had 66 known outbreaks, all of which were of variola minor, the mild form of smallpox.

#### *Asia*

In India and Nepal, the incidence of smallpox and the number of outbreaks decreased steadily. Nepal detected its last case in April and India in May. Bangladesh, however, was the site of yet another catastrophe as smallpox spread rapidly among the hundreds of thousands of persons displaced by floods and famine and from them to settled populations. Despite heroic efforts, the number of outbreaks increased from 78 in October 1974 to 1280 in mid-May 1975. India strengthened activities in border areas and quickly contained the 32 importations that occurred. Emergency funds made available by Sweden and several other countries permitted the recruitment of additional international staff for Bangladesh, and national mobilization by the Bangladeshi authorities resulted in 12 000 persons being fully engaged in eradication work. From May to August, the incidence in Bangladesh diminished rapidly but work had to be partially suspended in August, when the President of the country was assassinated. Officials feared civil war and yet another mass exodus of refugees. Fortunately, the country remained calm, smallpox eradication activities could be resumed, and on 16 October 1975 the last case occurred.

#### *Africa*

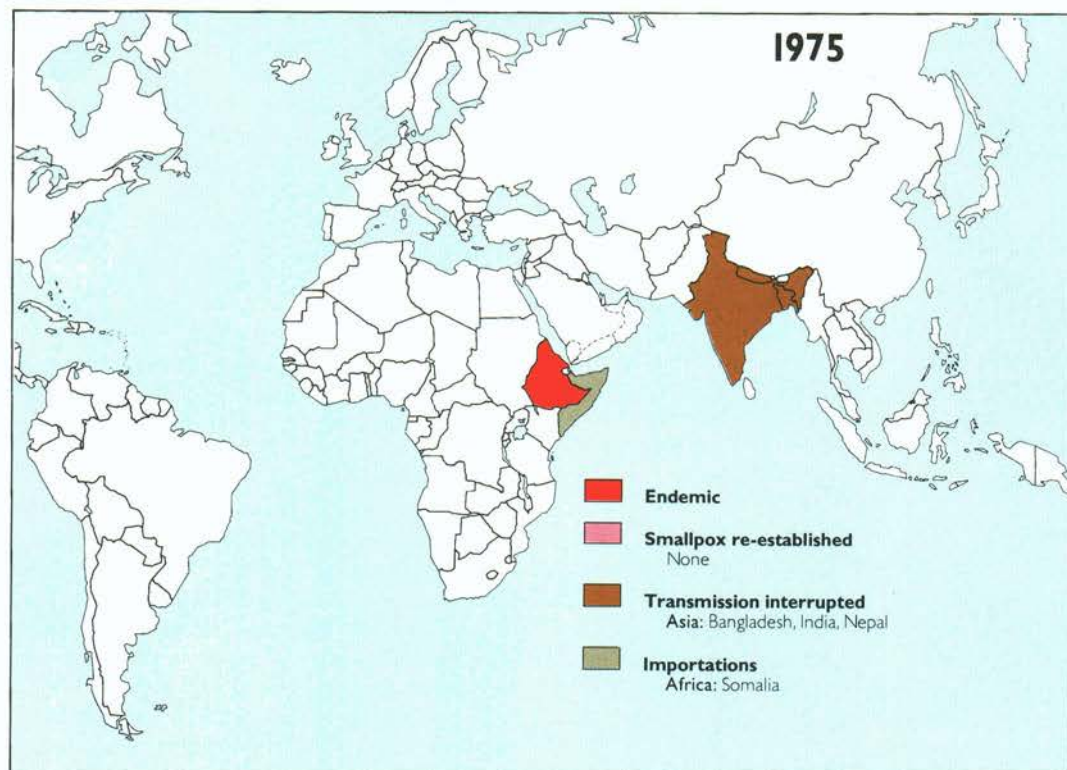

In Ethiopia, it had been expected that the eradication of smallpox would follow the same pattern as in other African countries, with transmission being interrupted 2-3 years after the programme began. By 1975, however, the Ethiopian programme had been

in operation for 4 years and although the staff were few in number, they were capable and strongly motivated. Surveillance-containment activities had been conducted since the start of the programme and more than 10 million persons had been vaccinated—nearly half of Ethiopia's estimated population. Although the population density was low and the habitations widely scattered, the mild variola minor continued to spread. The principal problem area was the rugged highland plateau, where resistance to vaccination was great and where large areas were periodically inaccessible owing to civil war. As a result of the eradication of smallpox from Asia, additional resources could be provided, permitting a 5-fold increase in staff, but the hostilities within the country hampered their efforts.

#### *Other developments*

Rumours of cases of suspected smallpox began to be received with considerable frequency from countries considered to be free of the disease. Even though they proved false, arrangements had to be made to investigate each rumour thoroughly and to publicize the findings in order to maintain confidence in eradication. Another emerging problem was that of designing and implementing an appropriate strategy to permit eradication to be certified in the African countries, some of which had detected no smallpox for many years and had consequently stopped their smallpox eradication activities. Certification of eradication in Africa had been deferred until the continent as a whole had become smallpox-free. In 1975, however, it was decided that because of the continent's vast size, the large number of countries, and the diminishing level of smallpox eradication activities, preparations for certification should commence as soon as possible. In February, the first of a number of planning meetings was held, this one being concerned with methods for certification in western and central Africa. This implied that eradication in Africa would be achieved, if not within the year, at least soon thereafter. At the end of 1975, however, that was by no means certain.

**Plate 10.50.** Smallpox in the world, 1975: eradication from continental Asia.

### The Achievement of Global Eradication, 1976-1977

As 1976 began, smallpox was known to exist in only 66 villages in Ethiopia but the interruption of transmission there and in Somalia, where it became re-established later that year, proved to be as difficult as it had been in mainland Asian countries in 1974-1975. Not until October 1977 was smallpox finally eradicated. A broad range of problems hampered the effort, from difficulties of topography and transport, civil war and eventually war between Ethiopia and Somalia, socio-cultural problems posed by nomads, variolators and large groups who resisted vaccination, to the suppression of reports of cases by the authorities in Somalia.

#### *Ethiopia*

Through mid-1976, the resources in Ethiopia were concentrated in the central and northern highland plateau areas in which civil war was raging and most outbreaks were occurring. At great personal risk to the staff concerned, these were gradually contained. Smaller numbers of staff worked in the sparsely settled south-eastern desert, where the few outbreaks occurred primarily among nomads. From past experience in similar areas of western Africa, it had been assumed, erroneously, that smallpox transmission could not long persist in such a scattered, mobile population. In the Ethiopian Ogaden desert, however, variola minor proved to be remarkably tenacious, and operations were frequently interrupted by warfare, the kidnapping of teams and the destruction of vehicles and helicopters. In August 1976, however, the last known outbreak in Ethiopia was contained and, for 7 weeks, no cases were reported from anywhere in the world.

#### *Somalia*

From 1972 until February 1976, Somalia had regularly reported importations from Ethiopia, but each was said to have been promptly detected. Late in September 1976, Somalia again reported several imported cases, this time in Mogadishu, the capital. It was learnt later, however, that these were but a few of many cases which were known to the authorities. WHO staff and consultants were quickly sent to help but they were not permitted to visit patients' houses or to travel outside the capital. Repeated mass vaccination campaigns throughout the city failed to

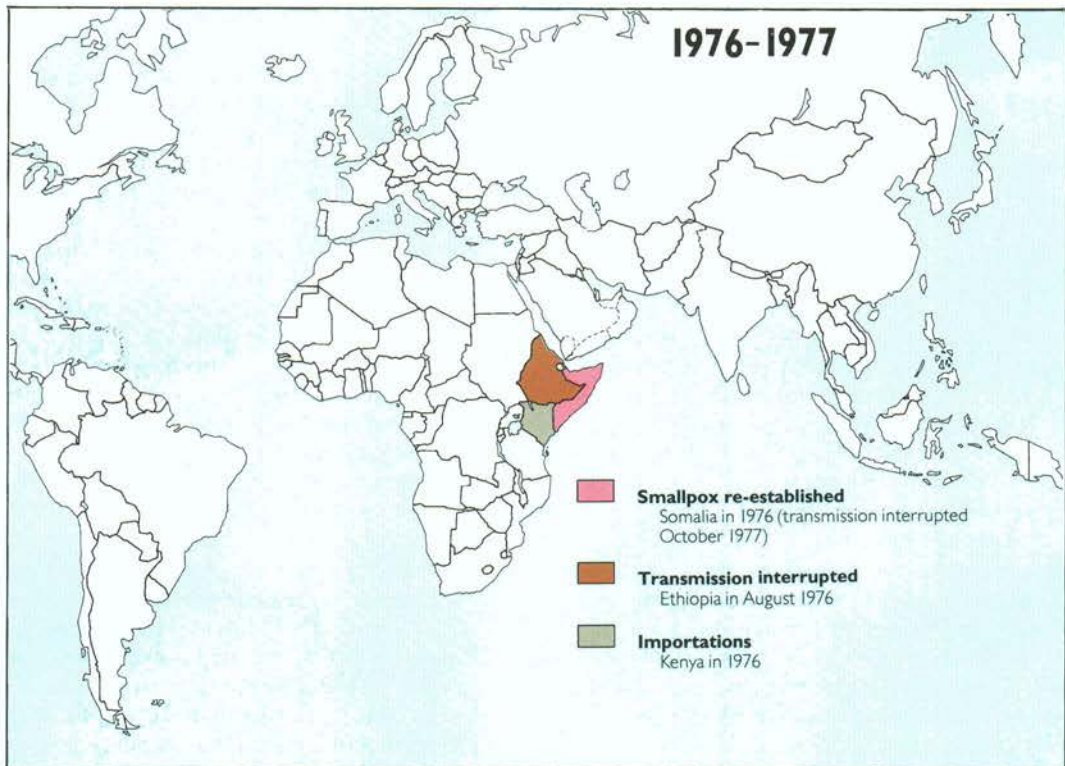

stop the spread of smallpox and fully 6 months elapsed before an effective national programme could be established. By then, the disease had spread widely throughout southern Somalia. A large-scale emergency effort was mounted that started in March 1977 and involved adjacent areas of Djibouti, Ethiopia and Kenya. More than 3000 cases were documented before the last case occurred on 26 October 1977.

#### *Other developments*

During 1976-1977, certification activities were organized in Asian and African countries, often requiring special studies lasting a year or more before a WHO international commission could be invited to assess the programme and to certify eradication. In April 1976 eradication was certified in 14 countries of western and central Africa, and in December in Afghanistan and Pakistan; in April 1977 in Bhutan, India and Nepal, in June in 9 countries of central Africa, and in December in Bangladesh and Burma.

It became apparent in 1977 that an independent body would be needed to advise on the measures that should be taken to give health authorities throughout the world sufficient confidence in global eradication to be willing to cease vaccination. A group of international experts, which was convened by WHO in October 1977, recommended a number of measures, including the designation by the Director-General of a Global Commission for the Certification of Smallpox Eradication. The Commission was to provide continuing guidance and oversight to the certification process and to report to the Director-General when it was satisfied that global eradication had been achieved.

The question of what should be done about the stocks of variola virus retained in laboratories around the world had long been a troublesome one. The destruction of most, if not all, such stocks was desirable but this required the full cooperation of national governments and of the laboratories concerned. As a first step, a register of the laboratories that held variola virus was prepared. Then, in 1977, the World Health Assembly requested that all variola virus stocks should be destroyed, excepting those held by WHO collaborating centres with maximum containment facilities. Many laboratories soon complied and events in 1978 served to speed the process.

**Plate 10.51.** Smallpox in the world, 1976-1977: global eradication.

### The Certification and Formal Declaration of Global Eradication, 1978-1980

The period between the containment of the last known outbreak and agreement by the Thirty-third World Health Assembly (1980) that global eradication had been achieved was as important but as difficult as had been the preceding years. The world community had to be confident of the attainment of eradication and had to know of the measures which had been taken to certify this. Laboratories had to be persuaded of the need to destroy their stocks of variola virus or to transfer them to WHO collaborating centres. Rumours of possible cases of smallpox had to be investigated and the findings publicized. Research was required to determine the nature of the viruses resembling variola virus which appeared to have been recovered from animals. An assessment of the risk of monkeypox to those living in the tropical rain forests was required as well as a determination of whether that virus could persist by human-to-human spread. Provision also had to be made for the long-term storage of vaccine reserves and for the preservation of records.

However important and substantial the activities which remained, the disappearance of smallpox quickly resulted in a diminished interest in the programme. Only with difficulty were national governments persuaded of the need to assign resources for certification activities, and WHO's budget for smallpox decreased sharply. Remarkably, however, a rigorously scheduled array of activities was completed almost as planned.

During 1978, certification activities were completed in 19 countries, including most of those in southern Africa and western Asia. This brought to 64 the total of countries where eradication had been certified by international commissions. In December, the Global Commission decided that special activities were needed in 15 additional countries. It also recommended that an official attestation be sought from all other countries to the effect that the country concerned had been free of smallpox for at least 2 years. Difficult diplomatic relationships, national sensitivities, civil disturbances and inertia caused serious problems in implementing the recommendations, but one by one the problems were overcome. On 9 December 1979, the Global Commission concluded that the global eradication of smallpox had been achieved and

approved a report that was presented to the Thirty-third World Health Assembly in May 1980.

The urgency for laboratories to destroy or transfer their stocks of variola virus became apparent when, in August 1978, 2 cases of smallpox with 1 death occurred as a result of a laboratory infection in Birmingham, England. National authorities took a greater interest in ensuring the safety of their own populations and the number of laboratories retaining stocks of variola virus decreased to 6 by May 1980, and eventually to 2.

In 1978, WHO announced a reward of US\$1000 for the report of any new case which could be confirmed as smallpox, and some 50 rumours a year were evaluated in 1978 and 1979 by field investigation and laboratory study. Most proved to be chickenpox; none was a case of smallpox.

Collaborative research on monkeypox and the "whitepox" viruses, conducted in laboratories in Japan, the United Kingdom, the USA and the USSR, revealed the troublesome "whitepox" viruses to have been laboratory contaminants. Field and laboratory studies of monkeypox virus provided increasing evidence that human infections were infrequent and that human-to-human transmission seldom occurred.

Reserves of smallpox vaccine were established and a protocol was developed for the periodic testing of samples to ensure their continuing potency.

Throughout this period, a special public information effort was undertaken to make widely known what had been accomplished and how, so that when the World Health Assembly agreed that eradication had been achieved, the general public would accept the fact more readily.

The declaration on 8 May 1980 by the Thirty-third World Health Assembly that smallpox eradication had been achieved concluded an historic chapter in medicine. Twenty-two years had elapsed since the USSR had first proposed to the Health Assembly that global smallpox eradication should be undertaken, and 14 years since the Assembly had committed special funds to a programme which it hoped would interrupt transmission within 10 years. In fact, 10 years, 9 months and 26 days elapsed from the beginning of the Intensified Smallpox Eradication Programme until the last case in Somalia.

## INTRODUCTION

Vaccination against smallpox had been practised in virtually every country of the world, and in many on a large scale, when the Intensified Smallpox Eradication Programme was launched in 1967. By its use, smallpox had already been eliminated as an endemic disease from all but 31 countries, which constituted the hard core of the smallpox problem. It was clear that, in order to implement the programme, one of the first tasks of the WHO Smallpox Eradication unit would be to ensure that enough vaccine was available, of sufficiently high titre and sufficiently heat-stable, to ensure that potent vaccine could be delivered to those needing vaccination in any place in the world, however remote and however adverse the environmental conditions.

Traditionally, smallpox vaccine had been distributed in liquid form, although laboratories in France and the Netherlands East Indies (now Indonesia) had produced air-dried or freeze-dried vaccines from the 1920s onwards. Unless refrigerated, liquid vaccine did not retain its potency for more than a few days whereas, until it was reconstituted, freeze-dried vaccine remained highly potent for over a month at ambient temperatures, even under tropical conditions. During the period after the Second World War, freeze-dried vaccine prepared in France was being used in francophone Africa and by the mid-1950s producers in several countries had developed freeze-dried vaccine production on a commercial scale. From 1959 onwards somewhat larger quantities of freeze-dried vaccine began to be used for smallpox vaccination in tropical countries, but its extensive use throughout the world dates from 1967-1968. After 1971 it was the only kind of vaccine used in any country engaged in a national smallpox eradication programme.

In May 1980 the Thirty-third World Health Assembly, after it had declared that smallpox had been eradicated throughout the world, recommended that smallpox vaccination should be discontinued, except for investigators at special risk. By 1985, smallpox vaccine production had been stopped in most countries and in no country in the world is smallpox vaccination routinely conducted in the civilian population. Vaccine reserves are being kept for emergencies by WHO and by the health authorities of some 20 countries (see Chapter 28). Thus smallpox vaccination has gone full circle. Introduced by Jenner in 1798, it came to be used all over the world until, with the eradication of the disease that it was designed to control, its use has now been abandoned, except for military personnel in some countries. Jenner's prediction, in the paper reproduced in Chapter 6, that "...the annihilation of the Small Pox, the most dreadful scourge of the human species, must be the result of this practice" has been fulfilled, making smallpox vaccination redundant.

An interesting sequel to this history of the rise and fall of smallpox vaccination is that vaccinia virus is currently showing considerable promise as a vector for genes specifying protective antigens against a variety of other infectious agents (see box). If the results of current research fulfil expectations, "smallpox" vaccine may make a comeback as a vehicle for providing simultaneous active immunization against a number of selected viral or protozoal diseases. It has the advantages of heat stability and ease of administration, but the risk of complications will need to be carefully weighed and perhaps a more attenuated strain sought (Quinnan, 1985).

In this chapter, various aspects of vaccine production and vaccination will be described in terms of practices that came into operation after the Intensified Smallpox Eradication

### Use of Vaccinia Virus as a Vector for Other Genes

The large genome of vaccinia virus contains a substantial amount of redundant DNA, as judged by the ability of mutants which have undergone large deletions to replicate in cultured cells and in animals (see Chapter 2). Furthermore, recombination and marker rescue occur in doubly infected cells. These properties opened the way for the construction of vaccinia virus hybrids, which contain genes for specified polypeptides of other viruses, bacteria or protozoa.

Several methods have been used to construct such hybrids. One method of general applicability (Mackett et al., 1984) is to construct plasmid vectors which contain the vaccinia virus thymidine kinase (TK) gene interrupted by selected restriction endonuclease cleavage sites placed adjacent to an appropriate promoter. The continuous coding sequence for a foreign (non-vaccinia) protein is then inserted in the TK gene plasmid so that the transcriptional start site of the vaccinia promoter is adjacent to that of the foreign gene. Cells in which vaccinia virus is replicating are then transfected with this plasmid, and homologous recombination takes place at the vaccinia TK gene. Since these recombinants are TK-negative, they can be readily selected and then tested for the presence and expression of the foreign gene.

Genes for antigens which play a role in protective immunity against several important viral diseases were tested in 1983 and 1984 and a high level of expression was found in both cultured cells and laboratory animals. This method has considerable potential for providing cheap and effective vaccination against several different human diseases that are common in developing countries, as well as against some diseases of domestic animals.

Programme had begun in 1967. Many features were common to the periods before and after 1967, but that year marked a turning-point, in that the global efforts to eradicate the disease necessitated modifications in production methods and in quality control of the vaccine, and also in vaccination techniques. In this chapter, unless otherwise specified, "vaccine" means the freeze-dried smallpox vaccine.

### VACCINE REQUIREMENTS FOR THE INTENSIFIED SMALLPOX ERADICATION PROGRAMME

#### Providing the Finance

The Intensified Smallpox Eradication Programme was launched in 1967 after the Nineteenth World Health Assembly in 1966 had voted an allocation of US\$2.4 million from the WHO regular budget. It was estimated that approximately 300 million persons would have to be vaccinated annually in the endemic and adjacent countries. At 1-2 US cents per dose, this would have cost US\$3-6 million for the vaccine alone, if WHO had provided all the vaccine required. Three other sources of vaccine were, however, already

available: (1) several of the endemic countries were producing large amounts of vaccine for local use; (2) following a resolution of the Twelfth World Health Assembly in 1959, a few producer countries were already making donations to WHO; and (3) vaccine was being supplied to developing countries through a number of bilateral aid programmes. WHO therefore decided that vaccine additional to that produced by the endemic countries or provided through bilateral aid and necessary for the implementation of the global smallpox eradication programme should be supplied entirely by voluntary donations. The annual allocation for smallpox eradication in the WHO regular budget could then be used exclusively for technical assistance: consultants, training, research and certain supplies and equipment including transport. This policy was retained throughout the Intensified Smallpox Eradication Programme. At the time (1967) it was thought that donated vaccine would constitute a relatively small proportion of the total requirement—namely, that needed to close the gap between the perceived need and available supplies. As the present chapter relates, the actual situation was found to be much more complex and difficult.

### Donations of Vaccine, 1958-1966

Apart from encouraging the establishment of national smallpox eradication programmes, the only important consequence of the resolution on global smallpox eradication adopted by the Twelfth World Health Assembly in 1959 (see Chapter 9) was the initiation of donations of smallpox vaccine, both to WHO and on a larger scale in bilateral assistance programmes. Between 1958 and 1966 the vaccine donated to WHO totalled 47 062 500 doses (from Jordan, Madagascar, Mexico, the Netherlands, the Philippines, Switzerland, Thailand, the USSR and the United Kingdom). Of this amount, 25 million doses of vaccine had been pledged by the government of the USSR in 1958 when it proposed that WHO should undertake a global smallpox eradication programme; they were delivered between 1960 and 1964. In bilateral donations between 1961 and 1966 the USSR also provided some 700 million doses of vaccine, which met the annual requirements of Afghanistan, Burma, India and some other countries during this period.

### Shortfalls in Vaccine—Quality and Quantity

Since, although smallpox vaccine had been in use since 1800, standardized vaccine production procedures and reliable assay methods for quality control were not developed until the 1950s (see Chapter 7), the quality of the vaccine varied significantly in different countries. Although the quality of vaccines donated to WHO had been tested since 1959, until 1967 such vaccines accounted for an average of only 7 million doses per year (Table 11.1), or less than 2% of the vaccine needed in endemic countries. The remaining vaccine was provided by domestic production or through bilateral aid programmes and by a number of producers who sold vaccine to the endemic countries. The titre of most of these vaccines was unknown to WHO and, even when known, the tests used to determine it were of uncertain reliability and conducted mainly by the production laboratories themselves. In many laboratories, the potency was tested by vaccinating 10 children and determining the proportion of takes, or by using the rabbit skin scarification method, which was imprecise; in addition, few laboratories tested the vaccine for heat stability.

Thus WHO was faced, not with the relatively small problem of closing a gap between the total requirement and supplies obtained from existing vaccine donors and local production of vaccine in the endemic countries, but with the much larger task of developing a production-donation system to serve most of the endemic countries and their neighbours.

Table 11.1. Quantities of smallpox vaccine distributed through WHO, 1958-1979

Year	Doses of vaccine (thousands)		
	Received	Distributed	Balance at end of year
1958	25 000	0	0
1959	0	0	0
1960	5 000	3 355	0
1961	2 000	7 420	0
1962	0	9 390	0
1963	98	7 528	0
1964	9 519	13 465	0
1965	1 637	1 897	0
1966	3 808	3 808	0
1967	15 820	14 807	1 208
1968	24 949	21 316	4 842
1969	21 370	20 686	5 526
1970	29 264	32 234	2 557
1971	51 544	44 741	9 360
1972	44 816	44 593	9 683
1973	52 023	34 676	26 930
1974	40 436	44 802	22 561
1975	33 841	36 310	20 092
1976	38 456	21 822	36 727
1977	6 408	23 657	18 935
1978	9 958	16 308	13 085
1979	35 090	4 940	43 235

As is shown in Table 11.1, vaccine donations to WHO were substantially increased after the Intensified Smallpox Eradication Programme was initiated in 1967. In the early days of the programme, one of the difficulties in increasing the amounts donated was that laboratories producing smallpox vaccine in most countries had only a limited capacity that was barely enough to meet their national programme requirements, let alone help to supply the very much larger amounts of vaccine needed for a global eradication programme.

Before 1967 provisions for testing the vaccine were complicated and slow, arrangements for shipping vaccine from the producers to the recipient country were complex and resulted in many delays, and WHO had no access to reserve supplies of vaccine for immediate shipment in an emergency. The problem was overcome when distribution was centralized through the Smallpox Eradication unit in Geneva.

### WHO SURVEY OF VACCINE PRODUCERS

Faced with the problems of meeting the basic requirement for smallpox eradication—namely, adequate amounts of a potent and stable vaccine and a system for distributing it to the countries in which it was needed—the Smallpox Eradication unit decided to conduct a survey of vaccine producers throughout the world. The objective was to gather information on the quality of the smallpox vaccines then in use and on the production capacity, production methods and the kind of quality control practised in different countries. This would provide a factual basis for introducing into vaccine production and use the changes needed to ensure that sufficient quantities of vaccine of suitable quality were available for the global eradication programme. Arita, then medical officer with the unit, took primary responsibility for this task.

In February 1967 the unit tried to identify all present or planned production facilities for freeze-dried vaccine and dispatched questionnaires (Plate 11.1) to the laboratories concerned, requesting information on the method of freeze-drying, the strain of vaccinia virus used, the method of growing the virus, the number of doses per vial or ampoule, and the results of testing. Of 77 laboratories contacted in 52 countries, 59 in 44 countries replied (Table 11.2). The information obtained by means of the survey is summarized below.

### Methods of Vaccine Production

In 51 of the 59 laboratories, vaccinia virus was harvested from the skin of calves (39) or sheep (12); 6 laboratories were producing vaccine from water-buffaloes, 3 on the chorioallantoic (CA) membrane of chick embryos

and 3 in tissue culture (bovine embryo fibroblasts). These results confirmed that smallpox vaccine of animal skin origin was by far the most extensively used throughout the world, in both developed and developing countries (Table 11.3).

Lyophilization equipment used in the different laboratories had been produced by at least 11 different manufacturers—in Czechoslovakia, France, the German Democratic Republic, the Federal Republic of Germany, Japan, the United Kingdom and the USA.

### Strains of Vaccinia Virus

Many different strains of vaccinia virus were in use for vaccine production, although it is probable that some of these had a common ancestry. Of the 59 laboratories that responded, 23 employed the Lister strain, 7 the New York City Board of Health strain, and 7 the Paris strain. The remaining 22 laboratories used a number of different strains, none of which was used by more than

3 laboratories (Table 11.4). Furthermore, it was doubtful whether all the strains were correctly described. For example, in a laboratory in Africa it was found that the strain used was a mixture of vaccinia and cowpox viruses. Moreover, the different passage histories of what were nominally the same strains of vaccinia virus undoubtedly resulted in substantial differences in their biological properties.

### Number of Doses per Container

In most countries there was, in general, little communication between those producing vaccine and those administering it in the field. Government laboratories were called on to produce a specified number of doses of smallpox vaccine each year, and the producers found it much less expensive to dry the vaccine in large ampoules. Likewise, commercial producers, who sold vaccine by the dose, preferred to package it in large containers. Few producers understood the logistic

problem that this posed for field staff, nor did they consider that, after reconstitution, much of the vaccine in large ampoules might be kept for a long time before being used (and thus lose potency), or else be discarded.

Ampoules and vials of various sizes were used in the different laboratories. Most producers regarded a "dose" as being 0.01 ml of reconstituted vaccine. About one-third of the laboratories supplied vaccine in containers of 2 or more different sizes, holding from 10 to more than 500 doses. More than 70% of vials on which the number of doses was indicated contained 100 doses or more.

### Initial Potency

Information was requested from each laboratory on the initial potency, heat stability and bacterial counts of the last 3 batches of vaccine produced. Of the 59 laboratories, only 31 reported that the initial potency of the vaccine met WHO standards (see Chapter 7) in all 3 production batches on which they were asked to report (Table 11.5). Even this figure may have been an overestimate, since the assays were carried out in the production laboratories and were not independently veri-

fied. In 48 laboratories, potency was measured on the CA membrane,  $1.0 \times 10^8$  pock-forming units per ml or higher being regarded as a satisfactory titre. Of these 48 laboratories, 2 recorded the potency in such a manner as to suggest that this assay procedure was not well understood, while 5 recorded results determined by the rabbit scarification technique, which was much less accurate than pock counting on the CA membrane.

### Heat Stability

The results of tests to determine the heat stability of the vaccine were much less satisfactory than those for initial potency, although heat stability was very important since most of the vaccine required for the global smallpox eradication programme was to be used in tropical regions. Only 16 out of 59 laboratories recorded satisfactory results for all lots tested (titre of not less than  $10^{8.0}$  pock-forming units per ml after incubation of dried vaccine at 37 °C for 4 weeks); 23 laboratories reported some or all lots to be unsatisfactory (Table 11.6), while 15 failed to report on heat stability, probably because the necessary tests were never carried out. Of the batches with unsatisfactory heat stability, the

<sup>a</sup> Viable non-pathogenic bacteria.<sup>b</sup> Unacceptable by WHO standards.

titre of about half was reduced to less than  $10^{7.5}$  pock-forming units per ml after heating.

### Bacterial Count

Since most smallpox vaccine was produced in animal skin, bacteriological sterility was not attainable. WHO standards required that the bacterial count should be less than 500 microorganisms per ml and that no pathogenic bacteria should be present. Satisfactory results were obtained in most laboratories (Table 11.7); of 138 batches on which reports were supplied, in only 12 was the maximum acceptable count exceeded. These came from 8 different laboratories, distributed over 4 continents. Of the 50 lots for which a bacterial plate count of zero (per ml) was recorded, 10 were produced in chick embryos or tissue culture, in 3 countries.

### ESTABLISHMENT OF THE WHO REFERENCE CENTRES FOR SMALLPOX VACCINE

The results of the survey confirmed early misgivings about the quality of the vaccine being supplied for use in endemic countries. It was clear that WHO needed a mechanism for the periodic testing of vaccine supplied to the eradication programme, whether by donation to the Organization, through bilateral assistance agreements or by local production in the endemic countries.

WHO does not have laboratories attached directly to it, either at Headquarters or in the regional offices. For purposes of quality control of the vaccine, therefore, the Organization had to make contractual service agree-

ments with appropriate laboratories whereby they would undertake to conduct specified tests.

In December 1966 the Connaught Medical Research Laboratories, University of Toronto, Canada, had accepted a contract from the WHO Regional Office for the Americas for the provision of technical services to improve the quality of smallpox vaccine being produced by laboratories in that region (see Chapter 12). The services involved included an evaluation of existing smallpox vaccine production facilities and their personnel in the region, the provision of training for production personnel, and advice on the selection of equipment necessary for the production and testing of smallpox vaccines being produced in the region. Dr Robert Wilson and Dr Paul Fenje, experts from the Connaught Laboratories, visited production laboratories in the region, especially in South America, where 11 laboratories were producing smallpox vaccine, many of them providing material that did not meet WHO standards, as judged by the survey conducted in 1967.

In 1967, similar arrangements were made by WHO with the National Institute of Public Health, Bilthoven, Netherlands, of which the Director-General was Dr Jan Spaander. The head of the vaccine laboratory was Dr Anton Hekker.

In 1969 the Connaught Laboratories were formally designated as the WHO Regional Reference Centre for Smallpox Vaccine in the Region of the Americas, and the National Institute of Public Health in Bilthoven as the WHO International Reference Centre for Smallpox Vaccine. The services provided by the International Reference Centre were as follows:

(1) To test smallpox vaccines submitted to WHO from different production laboratories.

(2) On the basis of the results of tests and special studies, to advise appropriately on the improvement of vaccine production methods.

(3) To collect, maintain and study, as indicated, strains of vaccinia virus from different parts of the world.

(4) To provide seed virus and national reference vaccine when required.

(5) To conduct research which could contribute to the improvement of vaccine production and testing methodology.

(6) To train virologists in the production and testing of smallpox vaccine.

Shortly after the 1967 survey, 20 laboratories in 20 different countries submitted samples of their vaccines to the WHO International Reference Centre for Smallpox Vaccine for testing. They included 4 laboratories in Asia, 8 in Europe, 3 in North Africa, 1 in south-western Asia, 3 in sub-Saharan Africa and 1 in the USA. The samples from 6 of these laboratories were intended for use in the eradication programme, through donation to WHO or bilateral assistance; the samples from the other 14 laboratories were from experimental production runs. It is reasonable

1968

**Plate 11.3.** Jan Spaander (b. 1914), Director-General of the National Institute of Public Health in Bilthoven, Netherlands, 1950–1980. He greatly facilitated the operations of the WHO International Reference Centre for Smallpox Vaccine established in the Institute.

to assume that most laboratories submitted samples that they expected would meet WHO standards.

Of the 35 batches actually proposed for use in the eradication programme, 22 failed to meet the initial potency or heat-stability requirements (Table 11.8). Some of these were from potential donors in the industrialized countries. Of the 39 batches submitted by producers intending to develop freeze-dried vaccine for use in their own countries or as a contribution to the global eradication programme, 25 failed to meet the WHO requirements. The conclusion was that in 1967 not more than 10% of the vaccine in use in endemic countries met WHO requirements, while the quality of the experimental batches was equally unsatisfactory.

### DEVELOPMENT OF IMPROVED VACCINES

The results of the survey, together with those of other tests on samples carried out by the WHO reference centres, indicated the urgency of strengthening vaccine production

Table 11.8. Independent testing in 1967 by the WHO International Reference Centre for Smallpox Vaccine in Bilthoven of production batches intended for use in the eradication programme or in experimental production<sup>a</sup>

Continent	Proposed for use in the eradication programme through donation to WHO or through bilateral contributions			Experimental production batches		
	Number of producers	Number of batches tested	Number of batches unsatisfactory <sup>b</sup>	Number of producers	Number of batches tested	Number of batches unsatisfactory <sup>a</sup>
Americas	1	1	1	0	0	0
Africa	1	1	0	5	21	19
Asia	2	11	9	3	6	4
Europe	2	22	12	6	12	2
Total	6	35	22	14	39	25

<sup>a</sup> In this and later tables, the designation of results as "satisfactory" or "unsatisfactory" was based on the following criteria for a satisfactory product (titres expressed in pock-forming units per ml):

Initial potency:  $\geq 10^{8.0}$

Heat stability, titre after 4 weeks at 37 °C:  $\geq 10^{8.0}$

Bacterial count (colonies per ml):  $< 500$

<sup>b</sup> Failed to meet WHO requirements in terms of initial potency or heat stability.

methods and quality control so that potent, heat-stable vaccine could be made available to the global programme.

A number of steps were therefore taken by the Smallpox Eradication unit to improve the quality of the vaccine and to ensure an adequate supply:

(1) organization of a Travelling Seminar on Vaccine Production in March 1968, which resulted in the production of a WHO document on production methodology;

(2) arrangement of visits to production laboratories by WHO programme staff and consultants;

(3) establishment of a reference vaccine;

(4) production of seed lots of Lister strain vaccine by the WHO International Reference Centre for Smallpox Vaccine;

(5) development of a rapid heat-stability test for the vaccine; and

(6) regular checking of vaccine potency and heat stability by the WHO reference centres.

### Meeting of Experts (March 1968)

Although the basic principles of vaccine production and testing had already been described in two issues of the WHO Technical

Report Series (WHO Study Group on Requirements for Smallpox Vaccine, 1959; WHO Expert Group on Requirements for Biological Substances, 1966), the steps in the production of smallpox vaccine had mostly been empirically developed. Little specific information about production methods had been published in the scientific literature. Furthermore, the survey had shown that unsatisfactory batches of vaccine were being produced in laboratories in developed and developing countries alike.

WHO usually handled such problems by arranging for a well-qualified consultant to visit and advise the appropriate institutions, in this case the producers whose vaccine had been found to be unsatisfactory. However, since there were then at least 20 producers supplying vaccine of substandard quality, it was difficult to recruit consultants who had the requisite experience and skills in the technical procedures and production management, and who would be able to devote the necessary time to such an operation. These considerations led the Smallpox Eradication unit to conclude that a better way to improve vaccine production rapidly would be to prepare a manual on the production of freeze-dried smallpox vaccine that would describe the simplest possible procedures for all stages of production and testing of a potent, stable and safe vaccine.

### Development by WHO of Quality Control of Smallpox Vaccine

In 1958 a resolution of the Eleventh World Health Assembly had stressed the importance of "thermostable smallpox vaccine" for use in tropical areas, and in 1962 the Fourteenth World Health Assembly invited countries to contribute freeze-dried vaccine to the WHO eradication programme. Thus WHO had to test donated vaccine before accepting it and began to do so in 1962. However, the arrangements did not cover other, much larger, amounts of vaccine being donated through bilateral assistance programmes or vaccine being produced in endemic countries for national programmes. In fact, the WHO Secretariat held the view that bilateral contributions and the way that they were used were the concern solely of the two countries involved, and that WHO should not intervene and had no authority to impose international quality control on domestic vaccine producers. These problems were addressed after the 1967 survey revealed that so many producers, in so many countries, were producing substandard vaccine. Using these data, the Smallpox Eradication unit initiated a continuing exchange of information with individual producers, who came to understand the importance of international quality control.

Another consequence of the WHO survey of vaccine quality was that the results led governments of many countries to recognize the deficiencies of the system by which producers themselves evaluated the quality of their products, and thus helped in the establishment in several countries of independent systems for the quality control of all biological products.

#### *Panel of experts*

Selected experts from the following laboratories were chosen to participate in a seminar held in Geneva in March 1968 and in activities related to the preparation of the manual on vaccine production:

Connaught Medical Research Laboratories,  
University of Toronto, Toronto, Canada

Moscow Research Institute for Viral Preparations,  
Moscow, USSR

National Institute of Public Health, Bilthoven,  
Netherlands

Research Institute of Immunology, Prague,  
Czechoslovakia

Wyeth Laboratories, Philadelphia, USA

At that time the first and the third laboratories were directly assisting the WHO eradication programme in testing vaccine samples; the fourth laboratory—in Prague—had published an important developmental study on smallpox vaccine; and the laboratories in the USSR and the USA were major producers of freeze-dried smallpox vaccine for the global eradication programme.

In the 1960s the Lister Institute, in the United Kingdom, was the leading laboratory in the technology of freeze-dried smallpox vaccine (see Chapter 7). Because funds for its

research were derived partly from the proceeds of the sale of its vaccine, the Institute turned down WHO's request to permit the participants in the seminar to visit the Institute, believing that the full disclosure of its technical knowledge might reveal trade secrets. However, the Director of the Lister Institute agreed to the appointment of Dr Colin Kaplan, then Director of its Vaccine Production Department, as a special consultant to the group. Early in 1968 exploratory discussions were held in Bilthoven between Dr Kaplan, Dr A. C. Hekker (Bilthoven), and Henderson and Arita (WHO), and a working paper on production methods, based mainly on those used in the Lister Institute, was prepared as a basis for discussions on the proposed manual.

#### *First meeting (19–23 March 1968)*

The first meeting of the group of experts, held at WHO Headquarters in Geneva, reviewed various aspects of production and testing. Working papers submitted by the participants provided information from each laboratory on the following topics: nature of seed lot used for production, virus titre at each

production stage from seed lot to final product, virus yield, heat-stability studies of final product, and level of bacterial contamination at various stages of production. Photographs showing the various production processes were examined, with a view to their inclusion in the proposed manual.

*Visits to laboratories and final meeting (28–30 March 1968)*

Immediately after the first meeting, the group of experts visited the Moscow Research Institute for Viral Preparations and Wyeth Laboratories, Philadelphia, two of the major vaccine contributors, to observe the production process and examine the production data. The final meeting was held at Wyeth Laboratories. The draft of the manual on the methodology of vaccine production was carefully reviewed in the light of the

visits. Agreement was reached on a document entitled *Methodology of Freeze-dried Smallpox Vaccine Production*, the first report to describe simple and practical methods for the production and testing of freeze-dried vaccine. Although never officially published, it contained all the necessary information at a level of detail not provided elsewhere and was made widely available as a document of the Smallpox Eradication unit (SE/68.3 Rev. 2), being distributed to all laboratories interested in the production of freeze-dried smallpox vaccine. Its contents are summarized below.

### Production of Freeze-dried Vaccine

#### *Choice of vaccinifer*

Although in 1968 the successful production of smallpox vaccine in chick embryos

**Plate 11.4.** Members of the Seminar on Vaccine Production, at the final meeting from 28 to 30 March 1968, at the Wyeth Laboratories, Philadelphia, Pennsylvania, USA. Left to right, front row: P. Fenje (Canada), S.S. Marennikova (USSR), A.C. Hekker (Netherlands), J.H. Brown (USA), R.J. Wilson (Canada) and I. Arita (WHO); back row: F.M. McCarthy (USA), M.Z. Bierly (USA), H. Tinc (USA), V.N. Milushin (USSR), A. Bernstein (USA), C. Kaplan (United Kingdom), D.A. Henderson (WHO), B.A. Rubin (USA) and A.K. Fontes (USA).

and in cultured cells had been reported, it was decided that the document should concern itself only with the traditional method, in which animal skin was used for the production of vaccine pulp, since this was far simpler and more straightforward. It was thought better to upgrade the method familiar to producers in developing countries than to suggest techniques that were comparatively new and that failed at that time to give a product of satisfactory heat stability.

#### *Strain of vaccinia virus*

It was recommended that a strain of vaccinia virus should be used which would induce adequate immunity in man with as few ill effects as possible, that it should produce compact, clearly visible white pocks on the

chorioallantoic membrane, thus making assay easier, and that unsuitable strains should be discarded. No particular strain was officially recommended but, in response to inquiries, the Smallpox Eradication unit advised that either the Lister or the New York City Board of Health strain should be used. The Lister strain was more widely used, because it produced pocks on the CA membrane that were easier to count and because the WHO International Reference Centre later produced seed lots of this strain for distribution to vaccine producers in developing countries (see below).

#### *Seed lots*

The principle of using seed lots (WHO Study Group on Requirements for Smallpox

WHO/L. DALE

WHO

**Plate 11.5.** **A:** Vaccine production in calf skin in Bangladesh, using the scarifier developed by Wyeth Laboratories, Philadelphia, Pennsylvania, USA. **B:** Enlarged view of scarifier.

Vaccine, 1959; see Chapter 7) was recommended and a practical method for preparing them was described. Slonim et al. (1969) showed that the viral concentration in the harvested pulp was 3 times higher when vaccinifers were scarified with an inoculum containing  $10^{8.3}$  pock-forming units per ml than with one containing  $10^7$  pock-forming units per ml. To provide a safety margin, the document stipulated that the titre of the seed lot should not be less than  $10^{8.7}$  pock-forming units per ml. This was substantially higher than the acceptable titre for vaccination, but was essential if adequate yields of high-titre vaccine were to be obtained.

#### *Preparation of vaccinifer*

A rigorous schedule for cleansing the animal skin was recommended, which substantially reduced the bacterial count to the extent that very few or no viable bacteria (and no pathogens) were found in the aliquot of vaccine (usually 1 ml) cultured.

#### *Scarification*

The recommended method of scarification was based on the experience of the participating producers, and an instrument for scarification of the vaccinifer in use in Wyeth Laboratories was produced by WHO and distributed to producers on request (Plate 11.5).

#### *Preparation of vaccine*

The method of extraction and treatment of the viral suspension was described with special reference to the specification of the required potency at each stage of the production. Phenol was added to a concentration of 0.5% by weight, following observations by Hekker & van Ramshorst (1969), who had investigated the phenol content and bacterial counts of 51 lots of freeze-dried vaccine from 23 laboratories in several countries and shown that this was the maximum concentration that would reduce the bacterial count without affecting initial potency or heat stability.

Before being dispensed into ampoules, the viral suspension was required to have a titre of at least  $10^{8.7}$  pock-forming units per ml, since the processes of freeze-drying and incubation at 37 °C for 4 weeks would somewhat reduce its potency. The final vaccine, after incubation, was required to have a titre of not less

than  $10^8$  pock-forming units per ml, in line with the standards established by WHO in 1965.

#### *Size of container used for vaccine distribution*

The volume of fluid to be dispensed into each final container was specified as between 0.15 ml and 0.25 ml, which would provide 15–25 doses per ampoule by the conventional scarification or multiple pressure techniques and 60–100 doses for vaccination with the bifurcated needle. Although ampoules providing fewer doses were requested by field workers, production experts agreed that 0.15-ml lots were the smallest practicable volumes that could be dispensed and dried.

#### *Reconstituting fluid*

Traditionally, glycerol had been used at a concentration of 40–60% in the suspending fluid of liquid vaccines. It had to be omitted from the fluid used to suspend the lymph for freeze-drying, but its properties made it useful for the reconstituted vaccine. Studies by Slonim & Röslerová (1969) showed that, at

**Plate 11.6.** Dimitrij Slonim (b. 1925), of the Institute of Sera and Vaccines, Prague, Czechoslovakia, contributed to methods for the accurate assay of vaccine and was a member of the Seminar on Vaccine Production.

temperatures above 0 °C, glycerol inactivated vaccinia virus at a rate that was proportional to temperature and glycerol concentration. It was suggested in the document that the reconstituting fluid should consist of a solution of 50% (v/v) glycerol in 0.004 M McIlvaine's buffer.

#### *Freeze-drying equipment*

The document provided advice on the advantages and disadvantages of the different types of freeze-drier available commercially (centrifugal and shelf; Plate 11.7), and the ampoules, vials and rubber stoppers appropriate for them.

### CONTINUING QUALITY CONTROL OF SMALLPOX VACCINE

Having established methods for the production of smallpox vaccine suitable for use in tropical countries, it was important that both WHO and national authorities should continue to test the vaccine provided, whether donated through WHO or through bilateral assistance or produced locally in the endemic countries.

#### Testing Samples of Vaccine

Between 1959 and 1967 the testing of samples of vaccine donated to WHO was a

**Plate 11.7.** Freeze-driers of the type used for the manufacture of smallpox vaccine. **A:** Centrifugal freeze-drier and secondary drier, with manifolds. **B:** Centrifugal carrier plate assembly. **C:** Sealing headers for ampoules on secondary drier. **D:** Shelf-type freeze-drier.

lengthy process, sometimes more than a year elapsing between the submission of a sample and the sending of a report on its potency to the producer. Two factors contributed to this delay. First, the testing arrangements were entrusted as additional work to the small Biological Standardization unit of WHO, whose normal duties involved the staff in frequent absences from Geneva; samples for testing and reports on potency had to await their return from duty travel. Secondly, the testing was carried out for WHO by the State Serum Institute in Copenhagen, which produced smallpox vaccine on a relatively small scale and for only a brief period each year; to rationalize its work, it usually tested samples from WHO at the same time as its own local production batches. This delay, which was unacceptable if the assays of vaccine quality were to be of any use, was eliminated when the responsibility for testing was transferred to the WHO reference centres for smallpox vaccine and the handling of samples and reports in Geneva was taken over by the Smallpox Eradication unit.

After 1968, all producers who donated vaccine to the eradication programme or who produced vaccine for national eradication programmes were requested to submit vaccine samples periodically for testing by WHO. In addition, laboratories developing the capacity to produce freeze-dried vaccine were encouraged to submit samples to WHO for testing, so that they could be advised, if necessary, on how to improve the quality of their vaccine. Between 1967 and 1984, 27 countries donated freeze-dried vaccine to WHO (see Table 11.15). Samples of all these donations were sent to WHO reference centres for testing. At later stages of the programme, when samples from producers consistently met WHO requirements, donations were accepted without advance testing, although samples were tested after the donation had been received, to confirm that it was of the desired quality.

For the quality control of vaccine produced locally in endemic countries, WHO smallpox eradication staff working for national programmes were actively involved in collecting and dispatching vaccine samples and, if the results of the assays carried out by the national laboratory and the WHO International Reference Centre were in agreement, the batches of vaccine from which the samples had been taken were dispatched for use in the field.

**Plate 11.8.** Nelja N. Maltseva (b. 1934), a member of the WHO collaborating centre in the Moscow Research Institute for Viral Preparations, USSR, was active in laboratory diagnosis and research and worked as a consultant on vaccine production in several countries.

### Visits by Consultants

Vaccine producers having problems in ensuring that vaccine quality met WHO requirements, starting new methods of production or modifying traditional production methods were encouraged to benefit from the advice of visiting WHO short-term consultants. Although many laboratories were engaged in vaccine production, only a few of the personnel concerned were sufficiently experienced to be able to suggest realistic improvements in production methods, since instruments and working procedures had to be adapted to the practical realities in developing countries. The 15 consultants and the countries they assisted are listed in Table 11.9. Over the period 1967-1979 they visited more than 20 laboratories.

Freeze-driers manufactured by Edwards High Vacuum, Crawley, Sussex, England, were widely used and, at the request of the Smallpox Eradication unit, technicians from this company visited producers to maintain and service equipment.

### Reference Vaccine

The International Reference Preparation of Smallpox Vaccine was established in 1962

Table 11.9. WHO short-term consultants and countries visited, 1967-1974

Name	Laboratory or position	Countries visited
Dr P. Fenje	Connaught Medical Research Laboratories, Toronto, Canada	South American countries (1966-1973)

Dr A. Hekker		

(Krag & Bentzon, 1963) and is held in the custody of the International Laboratory for Biological Standards, State Serum Institute, Copenhagen, Denmark. One ampoule contains 14 mg of freeze-dried vaccine. This International Reference Preparation was designed to be used for standardizing producers' own reference vaccines, which could then be used whenever testing was carried out. However, many producers, especially in developing countries, were unable to produce satisfactory working reference vaccines. The WHO International Reference Centre for Smallpox Vaccine therefore produced a special batch of freeze-dried vaccine, No. 6713-18, which had been titrated in parallel with the International Reference Preparation and had a titre of  $10^8$  pock-forming units per ml when reconstituted. A number of these ampoules were kept in Geneva at  $-15^\circ\text{C}$  and the rest at the WHO International Reference Centre; they were provided as required to vaccine producers in developing countries for use as reference vaccines.

### Seed Lots of Vaccine

It was recommended in the document *Methodology of Freeze-dried Smallpox Vaccine Production* that the seed lot system should be used (see box)—i.e., a reasonably large freeze-dried or frozen primary seed lot was to be maintained, from which secondary seed lots to be used in production runs were to be derived. These secondary seed lots were to be no more than 5 passages removed from the primary seed lot. However, in many laboratories the history of primary seed lots was unknown, and many were of low potency (less than  $10^{8.7}$  pock-forming units per ml) or were heavily contaminated, so that it was extremely difficult for certain producers to use the system.

In 1968, responding to a request from the Smallpox Eradication unit, the WHO International Reference Centre for Smallpox Vaccine overcame these difficulties by the production of a large secondary seed lot ( $\text{Li}_2\text{K}_2\text{G}$ ) from the Lister strain of vaccinia virus. This consisted of a large number of ampoules of freeze-dried virus, each of which after reconstitution contained 10 ml of virus with a titre of about  $10^9$  pock-forming units per ml. The Lister strain of virus used in this seed lot had been received from the Lister Institute in 1961 as a sheep lymph prepara-

### The Seed Lot System for Vaccine Production

"The seed virus system is one of the procedures necessary to ensure that each production lot of vaccine has the same desirable biological characteristics as the parent strain... [It] requires that primary and several secondary seed lots be produced and dispensed in sufficient numbers of containers to ensure an adequate supply of virus for inoculation for long periods of time. The secondary seed virus used for production is not to exceed the fifth serial passage of the primary seed virus; thus, each production lot of vaccine will not be more than six passages removed from the primary seed virus.

"The size of a seed virus lot is dependent upon the requirements of the production laboratory. Units requiring large volumes of seed virus during a short interval of time may find it necessary to prepare several passages of secondary seed lots in order to obtain the required volume of inoculum for production lots of pulp. Smaller production units may be able to utilize the second passage of the primary seed as the inoculum in the production of vaccine pulp.

"The primary and secondary seed virus lots should pass the standard tests for identity, safety and bacterial content... The potency of the primary and secondary seed virus should be as high as is practicable and assayed periodically (every three months) to ensure adequate potency following long-term storage. Seed virus with a potency less than  $5 \times 10^8$  p.f.u. per ml should not be used.

"Ideally, the primary and secondary seed lots should be freeze-dried in ampoules and stored at 4 °C or lower. However, an adequate supply of potent seed virus can also be maintained by the use of freeze-dried primary seed virus and the preparation of secondary seed virus as glycerolated suspensions (50% glycerol in 0.004 M McIlvaine's buffer) which will retain adequate potency for one year when stored at -20 °C." (From *Methodology of Freeze-dried Smallpox Vaccine Production*; SE/68.3 Rev. 2.)

tion, and had been passed twice on calf skin. Second-passage material was lyophilized in 10-ml amounts as seed virus for the production of smallpox vaccine. Thus, the vaccine in the seed lots prepared for international distribution was the second passage on calf skin, and had a high viral content. These seed lots were distributed on request to producers and often used immediately for the inoculation of vaccinifers, so that the production process was accelerated. The availability of this material was partly responsible for the widespread use of the Lister strain of vaccinia virus from 1969 onwards (see Table 11.21).

These two products, the working reference vaccine and the secondary seed lot ampoules, greatly simplified procedures and assisted producers who were encountering difficulties. When supplied, they were always accompanied by special instructions on the potency testing of smallpox vaccine, as outlined below in the section on assay technique.

### Evaluation of Testing Methods

#### *Rapid heat-stability test*

During the first 3 years of the Intensified Smallpox Eradication Programme, substantial efforts were made to ensure the flow of adequate supplies of vaccine to national smallpox eradication programmes. All vaccine, however, was tested in order to ensure that its quality was satisfactory. The bottleneck in the standard testing procedures was the heat-stability test, which took not less than a month, because of the need to assay the vaccine after 28 days at 37° C. Cross et al. (1957), however, had demonstrated the feasibility of determining stability by assaying potency before and after heating at 100 °C for 1 hour.

In 1969, Arita, in collaboration with the WHO International Reference Centre for Smallpox Vaccine, compared the results of

heat-stability testing of 139 batches of vaccine by the conventional 4-week test at 37 °C and the 1-hour boiling test (Fig. 11.1). Preparations with an initial titre of over  $10^{8.5}$  pock-forming units per ml and a titre of more than  $10^{7.5}$  pock-forming units per ml after boiling always met the standard requirements for heat stability (Arita, 1973). Accordingly, after 1969, the testing procedures at the WHO International Reference Centre were modified. Vaccine samples were first tested for stability by incubation at 100 °C for 1 hour; if the vaccine met the requirements noted, it was regarded as acceptable. Vaccine which failed to pass this screening test was further tested by the conventional heat-stability test.

This approach greatly speeded the testing procedures. Between 1969 and 1972, of 337 batches tested by this method by the WHO International Reference Centre, 224 (67%) were found to be acceptable. This method was also used in India (Sehgal et al., 1969; Sehgal & Singha, 1972). For reasons unknown, vaccine produced in Bangladesh in vials rather than ampoules and Iranian vaccine prepared in ampoules consistently failed the

boiling test, although these vaccines were usually acceptable by the standard heat-stability test. They were therefore selectively tested only by the standard heat-stability method.

#### *Discrepancies between test results*

As the testing services developed, the Smallpox Eradication unit took great pains to determine the causes of discrepancies sometimes encountered between the results of potency tests carried out in the WHO International Reference Centre and in individual production laboratories. These investigations often led to improvements in the manufacturers' potency testing procedures and also helped to maintain their confidence in the results obtained by the centre. When a discrepancy occurred, the test was repeated in order to determine whether the difference in titres was, in fact, significant. Use of the centre's reference vaccine, which was distributed to all producers on request, also helped to solve such problems.

#### *Assay technique*

Some discrepancies resulted from apparently minor differences in the procedures used for assaying vaccine on the CA membrane. For instance, it was recommended (WHO Expert Group on Requirements for Biological Substances, 1966) that: "At least ten chick embryos, each of about 12 days' incubation, shall be divided into two equal groups. To the chorio-allantoic membrane of each embryo of the first group, 0.1 ml or 0.2 ml of a suitable dilution of the vaccine shall be applied." In this context, some producers were using 12-day-old embryonated eggs and some 13-day-old eggs, or 11-, 12- or 13-day-old eggs as available. Some producers used an inoculum of 0.1 ml, others one of 0.2 ml.

Dr Alan Bernstein (Wyeth Laboratories) studied the titre of smallpox vaccine as a function of the number of days of incubation of the embryonated eggs (10, 11, 12, 13 or 14 days). The younger the embryo used for the assay, the lower was the apparent titre of the vaccine (Table 11.10). The use of eggs only 1 day younger or 1 day older than 12 days changed the titre by as much as -0.6 to +0.4 log unit respectively. Differences were also observed when inocula of 0.1 and 0.2 ml were used (Slonim et al., 1967). Because of these

Fig. 11.1. Comparison of the rapid screening test (100 °C for 60 minutes) and the conventional heat stability test (37 °C for 4 weeks). Open circles: acceptable by conventional test; closed circles: unacceptable by conventional test. (From Arita, 1973.)

findings, an inoculum of 0.1 ml and an incubation period of 12 days for the eggs were accepted as standard.

It was also suggested that the quality of the eggs from different geographical areas might affect the assays. For reasons unknown, vaccines assayed in developing countries often gave titres 0.2-0.3 log unit lower than when tested by the WHO reference centres, a not unwelcome circumstance, as it ensured with greater certainty that the vaccine used in the field was fully potent.

To ensure comparability of results, it has been decided that assay by pock counting on the CA membrane will be used for as long as it is necessary to test samples from the vaccine reserves held in Geneva and Lausanne (see Chapter 28).

Fig. 11.2. Decline with time in titres of samples of smallpox vaccine of different moisture contents kept at 24 °C. The relative effects were comparable at 37 °C, but the decline in titre at all moisture contents higher than 0.36% was greater. (From Sparkes & Fenje, 1972.)

### Moisture content

Although residual moisture appeared to be an important factor influencing the stability of freeze-dried vaccine, it was difficult to establish criteria for the moisture content. Sparkes & Fenje (1972) studied the decline with time in the potency of freeze-dried vaccine with moisture contents ranging from 0.36% to 6.7%, at temperatures of 4 °C, 24 °C, 37 °C and 100 °C (Fig. 11.2). They concluded that a residual moisture content of less than 1% was essential for the satisfactory storage of freeze-dried smallpox vaccine at ambient temperatures. However, the test for moisture content was too expensive and technically too difficult to use as a routine, and samples with too high a moisture content rarely passed the heat-stability test. The moisture content was sometimes assayed with batches of low heat stability to determine whether this was due to inadequate freeze-drying.

### Improvements in Vaccine Quality

#### General

The Intensified Smallpox Eradication Programme marked the first time in the history of WHO that an effective world-wide quality control programme for biological products had been established (Fig. 11.3). Between 1967 and 1980, 2578 production batches were tested, the annual number of samples ranging from 392 in 1973 to 46 in 1980 (Table 11.11). From 1969 onwards there was a considerable improvement in vaccine quality. Between 1967 and 1972 initial potency was unsatisfactory in 47% of instances, heat stability in

1975	21	167	139 (83)	28 (17)	15	10	6
1976	16	213	203 (95)	10 (5)	2	7	3
1977	11	114	101 (89)	13 (11)	1	12	1
1978	9	59	57 (97)	2 (3)	0	2	0
1979	10	85	82 (96)	3 (4)	3	1	0
1980	5	46	46 (100)	0 (–)	0	0	0
Total	–	2 578	2 130 (82.6)	448 (17.4)	208	229	48

43% and bacterial count in 10%. From 1973 onwards the initial potency was usually satisfactory but heat stability remained an occasional problem.

Of 1842 batches tested between 1967 and 1976 and classed as satisfactory, an average of 10% were of "borderline" potency after heating—i.e., the potency was between  $10^{7.8}$  and  $10^{8.0}$  pock-forming units per ml. Only one borderline batch was found after that date.

In addition to this regular quality control of vaccine provided by production laboratories, staff of national smallpox eradication programmes sent samples of vaccine from the field for testing if the expiry dates had passed, or if shipments had been delayed or mishandled so that their potency might have been adversely affected (Table 11.12). If the samples tested met the standards of potency and stability, the expiry dates for that batch were extended for another year. After 1970

Table 11.12. WHO quality control of freeze-dried vaccine used in the Intensified Smallpox Eradication Programme: results of tests carried out in WHO reference centres for smallpox vaccine in Bilthoven and Toronto on samples submitted from the field

Year	Number of producers	Number of batches submitted	Number satisfactory (%)	Number unsatisfactory	
				Initial potency	Heat stability

Total	-	377	279	79	19

there was a general improvement in quality, suggesting that vaccine supplies were being more carefully handled in the countries in which they were used.

#### Results in different regions

By 1971 the quality control operation covered 41 laboratories producing vaccine for national eradication campaigns, for donation to WHO or for bilateral assistance to endemic

countries. Although there was a distinct overall improvement, problems continued to occur. Table 11.13 shows the results of quality control tests by WHO reference laboratories of batches produced during the period 1971-1974.

In South America, Brazil was the only country in which smallpox was still endemic in 1967, but the quality of the vaccine produced in 3 of its 4 production laboratories, most of which was grown in eggs, often failed

to meet WHO standards, especially for heat stability (see Chapter 12). Smallpox was nevertheless eradicated from the country, primarily because of the care exercised by staff in the storage and transportation of vaccine.

Producers in North America supplied large amounts of vaccine of good quality to the global programme. However, during the early stages of the programme there were problems of lower potency with some batches produced in the USA for jet injectors. In 1974, some batches of vaccine from Canada were also found to be of unsatisfactory potency. However, these were very occasional failures and the quality was quickly improved when the deficiencies were drawn to the attention of the producers.

In Africa, vaccine from Guinea and Kenya was of good quality and was used in their national programmes, some also being donated to other African eradication programmes. Production facilities that had been established in Ethiopia, Rwanda and Zaire soon discontinued production because of unsatisfactory results in tests of vaccine samples and an assessment by consultants that the production problems could not be readily overcome. Efforts were made to improve the quality of vaccine produced in the Nigerian laboratory, but these proved unsuccessful.

In the WHO Eastern Mediterranean Region, excellent vaccine was produced in Iran from 1972 onwards and was used both for the national vaccination programme and in Pakistan, through donation to WHO. Samples of good-quality vaccine were also received from the Syrian Arab Republic, beginning in 1973, but no other laboratories in this region were successful in producing satisfactory freeze-dried vaccine.

In South-East Asia, excellent progress was made in 8 production laboratories in 4 countries, the results of testing after 1971 being generally satisfactory.

Samples from the 4 laboratories in the Western Pacific Region which produced vaccine for their own use or for donation were all satisfactory.

All the European producers enumerated in Table 11.13 produced vaccine for donation to WHO, a sample of each batch being sent to the WHO International Reference Centre for confirmation of their own assay results. A few batches from the USSR tested before 1971 failed to meet WHO requirements, as did a few batches sent from Switzerland in 1972. Since the 2 laboratories in question were

major suppliers of vaccine to the global smallpox eradication programme, the failure of these batches to meet the requirements was of concern to both WHO and donor governments. Following an intensive review of procedures, the quality of vaccine supplied by both laboratories improved so that WHO requirements were regularly met.

From 1973 onwards there was enough good-quality vaccine, produced locally or donated to WHO, both to cover adequately the needs of endemic countries and to extend the supply to adjacent countries at risk, as well as countries in which maintenance vaccination was continuing.

Experience with this quality control programme provides some useful lessons. First, even sophisticated laboratories in the industrialized countries produced substandard vaccines—albeit infrequently—indicating that all vaccine must be subject to quality control. Secondly, with adequate technical advice, certain laboratories in endemic countries were successful in producing high-quality

1978

**Plate 11.9.** Anton C. Hekker (b. 1928) was head of the WHO International Reference Centre for Smallpox Vaccine at the National Institute of Public Health, Bilthoven, Netherlands, established in 1967. He provided invaluable help in ensuring effective quality control of vaccine used in the global smallpox eradication programme and in helping manufacturers in endemic countries to produce high-quality vaccine.

vaccine in large quantities. Lastly, quality control contributed to the decision by a number of governments to discontinue production when it became apparent that their vaccine failed to meet WHO standards.

### VACCINE PRODUCTION IN ENDEMIC COUNTRIES

In the interests of self-sufficiency, many endemic countries wished to embark on the production of freeze-dried smallpox vaccine. For all or even most to do so would have been uneconomical in scale of production. Thus, it was necessary to develop a policy based on population size, so as to limit the number of countries to which WHO assistance would be provided.

"If a laboratory is suitable for upgrading to enable it to make freeze-dried smallpox vaccine, it should be equipped to produce at least 500 000 containers a year, each containing 0.25 ml of vaccine. This is equivalent to about 125 litres [12.5 million standard doses]. Countries not planning to produce this quantity of vaccine annually would be ill-advised to initiate production." (*Methodology of Freeze-dried Smallpox Vaccine Production*; SE/68.3 Rev.2.)

For example, vaccine production in a country with a population of less than 10 million would be uneconomic, since in such a country only 2 or 3 million doses of vaccine would be required annually, an amount that would ordinarily be produced in 10 or 15 production batches, in a few months. Such a production effort would not justify the necessary investment of manpower, equipment and WHO training resources.

However, local production in the larger endemic countries was of the utmost importance, since such large amounts of vaccine were needed. For example, the combined population of Bangladesh, India and Indonesia in 1972 was estimated to be about 762 million—i.e., roughly half the population of all the countries in which smallpox was endemic in the late 1960s. Both WHO and UNICEF provided substantial assistance to these countries, each of which produced large quantities of vaccine and became self-sufficient (Table 11.14). Indeed, in the later stages of the campaign, India became a vaccine donor (see Table 11.15).

During the mid-1960s, a number of laboratories in Africa produced liquid vaccine and some endeavoured to convert to the

<sup>d</sup> Bangladesh and India certified smallpox-free.

production of freeze-dried vaccine, but only a few were successful. WHO provided support to 3—Guinea, Kenya and Nigeria—but only the first 2 were successful in consistently producing satisfactory vaccine. In addition, Mozambique and South Africa produced satisfactory freeze-dried vaccine.

Of the WHO-supported efforts, that of Kenya was the most successful. The laboratory in Kenya had been producing liquid vaccine for its own use and for sale to other countries in eastern Africa since the 1930s. The Smallpox Eradication unit, thinking that it might be possible to develop regional centres for vaccine production, took Kenya as a possible model. In practice, an unforeseen economic problem arose in developing the laboratory as a regional resource. To encourage the use of freeze-dried vaccine, it was WHO's policy to provide it free of charge to endemic countries. However, Kenya needed to recover the set-up and production costs of vaccine it supplied to other countries. Yet these countries could hardly now be asked to buy freeze-dried vaccine from Kenya when other countries received their vaccine free through WHO.

The problem was solved by supplying Kenya with materials needed to produce all of its freeze-dried vaccine, thus offsetting needed expenditures for additional vaccine production for donation to other African countries. Between 1967 and 1977 some 28

million doses were produced in Kenya, of which over half was donated to WHO.

Because of its small population (4.1 million in 1972), Guinea did not meet the criteria for WHO assistance for vaccine production, but the WHO Regional Office for Africa was persuaded by the government of Guinea to arrange for substantial WHO assistance, in terms of visits by consultants, freeze-driers, vaccine containers and reagents. Some 1.8 million doses produced in Guinea were eventually donated to the Intensified Programme in 1974 and 1975, but to all intents and purposes production ceased in 1971, when the WHO technical officer working with the project left the country after completion of his assignment.

Mozambique, while still an overseas province of Portugal, consistently produced satisfactory freeze-dried vaccine, and South Africa began producing a satisfactory freeze-dried vaccine in 1970.

In the South-East Asia Region, WHO consultants frequently visited the 4 Indian producers (in Belgaum, Hyderabad, Guindy (Madras) and Patwadangar) as well as those in Bangladesh, Burma, Indonesia and Thailand (see Table 11.9). UNICEF joined with WHO in supplying equipment, spare parts and other supplies, and by 1971 all were making vaccine that met WHO requirements.

In western Asia, efforts in Pakistan (then West Pakistan) to develop national vaccine production were not successful and the eradication programme there relied on donated vaccine. After 1972, good-quality vaccine was produced in Iran, which donated 26 million doses to WHO between 1973 and 1979. Enough vaccine for national needs was produced in the Syrian Arab Republic by 1973.

### DONATIONS OF VACCINE AND THEIR DISTRIBUTION

A total of 465 million doses of vaccine, worth US\$8.5 million, were donated by 27 countries to the Intensified Smallpox Eradication Programme between 1967 and 1984 (Table 11.15). Some 100 million doses remained at the end of the Programme, and are now kept as part of the WHO emergency vaccine reserve for the post-eradication era (see Chapter 28).

The amounts of vaccine distributed annually to 70 countries or organizations between 1967 and 1979 have been given in Chapter 10,

<sup>c</sup> 100 million doses of multipuncture vaccine donated by Belgium, the German Democratic Republic, India, Iran, the Netherlands, and the USSR which were not required for the eradication programme are kept in the WHO vaccine reserve in Geneva and Lausanne. Unused vaccine for jet injection has not been retained.

Table 10.9. Between 15 and 45 million doses of vaccine were dispatched annually to the endemic countries, in addition to the very substantial quantities that were produced locally or donated through bilateral aid programmes.

The problems of effectively distributing the small amounts of vaccine that were donated to WHO between 1958 and 1966 were resolved by centralizing distribution through the Smallpox Eradication unit, which rented cold-storage space in Geneva. Each country that had pledged donations of vaccine was asked to send such donations to the unit as soon as they were available. Charts assessing current and future vaccine requirements for all countries were drawn up. When a request was received from a country, the

vaccine required was immediately dispatched by airfreight. During holiday periods, such as Christmas or Easter, special arrangements were made by WHO supply services to ensure that vaccine, if urgently required, could be sent on the earliest possible flight.

Despite these arrangements, the quantity of the vaccine held in stock in Geneva was always small, and often inadequate to meet unexpectedly large demands. It was often possible to send to a country only enough vaccine for 2-3 months' operations, and often donated vaccine was dispatched as soon as it was delivered to Geneva. The situation was especially serious in 1972, when smallpox spread across Iran, Iraq and the Syrian Arab Republic, the demand for vaccine from these countries alone reaching 17 million doses. The situation became acute when the outbreak spread to Yugoslavia, which did not have enough freeze-dried vaccine to deal with the problem. Emergency appeals for donations were made, and the half million doses of vaccine in WHO cold storage were all dispatched to Yugoslavia. Only from 1974 onwards was a sufficient quantity of vaccine able to be held in Geneva.

Most vaccine was dispatched through Geneva, but in some areas it proved practical and more economical to send the vaccine direct from the producer to the recipient country. Thus donations from Kenya were sent direct to other African countries, from Iran direct to Pakistan, and from India direct to Bangladesh, Nepal and Sri Lanka. Several countries in South America assisted each other, as the need arose.

## NEW VACCINATION TECHNIQUES

The traditional techniques of vaccination as practised in the early 1960s have been described in Chapter 7. Two new vaccination techniques were introduced in the Intensified Programme: intradermal inoculation by the jet injector in 1967 and multiple puncture inoculation with the bifurcated needle in 1968.

### The Bifurcated Needle

Soon after its development and testing, the bifurcated needle (see Plates 11.14 and 11.15) became the standard instrument for vaccina-

tion in the global smallpox eradication programme. Its use simplified vaccination procedures, reduced the quantity of vaccine used and gave a better take rate than earlier vaccination techniques.

### History

Liquid vaccine was usually dispensed in sealed capillary tubes containing either one or several doses of vaccine. With single-dose capillaries, the ends were broken and the vaccine applied directly to the inoculation site. With multiple-dose capillaries, the ends were broken and the vaccine was usually put on a plate, from which it was taken up by a glass rod or the vaccination instrument itself and applied to the skin, to be followed by vaccination by scarification (scratch inoculation) or multiple pressure.

When manufacturers produced freeze-dried vaccine in the 1950s, it was packaged in multidose vials or ampoules, in which the vaccine was reconstituted when required by the addition of sterile diluent. A glass rod was dipped into the container and a droplet of the reconstituted vaccine transferred to the surface of the skin, after which vaccination by scarification or multiple pressure was carried out with a lancet or needle. Since this procedure was rather complicated for use in the field, several manufacturers, including Wyeth Laboratories, Philadelphia, the major producers of vaccine in the USA, sought a better method for transferring vaccine from

the vial to the skin. Many types of instrument were tested (see box), resulting ultimately in the development of the bifurcated needle, which was found to produce successful results even when used by vaccinators with little training.

The bifurcated needle was invented by Dr Benjamin A. Rubin of Wyeth Laboratories, and tested in the field by Dr M. Z. Bierly, who used the conventional multiple pressure method in order to evaluate its efficacy. The needles were patented under United States Patent No. 3 194 237 on 13 July 1965, but Wyeth Laboratories waived all royalties for needles manufactured under contract with WHO.

### *Use of bifurcated needles in the global smallpox eradication programme*

The simplicity of the bifurcated needle as a means of transferring vaccine to the skin and carrying out the vaccination was most attractive but, before recommending its use, WHO organized several studies to ensure that it would be effective in the variety of circumstances met with in various national smallpox eradication programmes. Ladnyi, then a WHO intercountry smallpox adviser in Nairobi, Kenya, Dr H. Mayer, a WHO intercountry smallpox adviser in Monrovia, Liberia, Dr E. Shafa, the regional smallpox adviser in the Eastern Mediterranean Region, and Henderson and Arita from the Smallpox Eradication unit at WHO Headquarters arranged to undertake these studies (SE/72.5). The most important development was the introduction of a new method of vaccination, by multiple puncture rather than multiple pressure.

*Vaccination by multiple puncture.* Traditionally, vaccine was introduced into the Malpighian layer of the epidermis either by scarification with a needle or lancet or by multiple pressure inoculation with a straight surgical needle (see Chapter 7, Fig. 7.2). Multiple puncture was impossible with a sharp surgical needle because it would penetrate too deeply; moreover, there was a belief that if blood was drawn vaccination was less efficacious. However, the flat prongs of the bifurcated needle prevented too deep an entry into the dermis. Experiments soon showed that the multiple puncture method, in which the bifurcated needle was held at right angles to the skin, which was then punctured several times with the prongs (Plate 11.14), was very efficient and very easy even for an illiterate

**Plate 11.13.** Benjamin Arnold Rubin (b. 1917) invented the bifurcated needle while working at Wyeth Laboratories, Philadelphia, Pennsylvania, USA.

### Development of the Bifurcated Needle

The bifurcated needle was the result of a developmental study by staff at Wyeth Laboratories but the original idea can be traced back to the early 19th century (D. Baxby, personal communication, 1983). "This operation [vaccination] is usually performed with a common lancet: but one which is fissured by a longitudinal slit, like a writing pen, succeeds rather better" (Moore, 1817).

Of the needle's more recent history, B. A. Rubin (personal communication, 1980) wrote:

"In 1961, I started to test new methods of dispensing the vaccine while also considering the methods of scarification. I collaborated with the Reading Textile Machine Company (now a division of Rockwell International) in needle design. We experimented with various textile needles and filament guides with standard openings as methods for dispensing vaccine. It then occurred to me that a pronged needle would retain the capillary activity of a loop, and that it might have simultaneous utility in scarification. I therefore suggested the use of a sewing needle in which the loop end was ground down to give a pronged fork. A system was devised in which a piece of wire was cut to the right length, and then stamped to give the fork shape, with such dimensions so that the prongs would hold exactly 1 mg of water by capillarity. The machine company then used a mass tumbling system that could sharpen the prongs of the forks of large numbers of needles.

"The sharpened fork was retested and found to hold 1 mg of water quite firmly. When tested with reconstituted lyophilized vaccine, the retained volume tended to be somewhat greater because of the increased viscosity. But the liquid vaccine adhered firmly to the needle. Thus, when the bifurcated tip of the needle is dipped into the vaccine, a constant amount is suspended between the prongs, ready for inoculation."

vaccinator to learn. It became the standard method of vaccination throughout the world.

It was observed that, if certain vaccinators recorded more vaccination failures than expected, it was often because they were too gentle, partly because of the above-mentioned belief that bleeding at the inoculation site reduced the take rate. However, experience showed that this belief was unfounded, and vaccinators were advised to use the multiple puncture method with the bifurcated needle with enough force to cause slight bleeding.

*Take rate.* Tests carried out in Egypt, Kenya and Liberia (Table 11.16) showed that take rates by the multiple puncture method were in the range of 98–100% in primary vaccinations and that reactions specified as major (see Chapter 7) occurred in 56–82% of revaccinations. In experiments by Dr Shafa in Egypt, in which the same individuals were inoculated on opposite arms by different methods the take rates for revaccination by scarification were slightly lower than those obtained with the bifurcated needle.

*Amount of vaccine.* The amount of reconstituted vaccine taken up by the bifurcated needle was tested in the Smallpox Eradication

unit in Geneva and the results were confirmed in the field. It was estimated that one dip of the needle point lifted an average of 0.0025 ml of reconstituted vaccine between the prongs. Since the amount of reconstituted vaccine used in conventional vaccination was about 0.01 ml, vaccination with the bifurcated needle saved vaccine, permitting 4 times as many vaccinations to be administered with a given quantity of vaccine.

*Design of the bifurcated needle.* The original needle developed by Wyeth Laboratories was designed to be used once only and then discarded. However, for the global eradication programme it was essential to be able to reuse the needles several times and to make them as cheaply as possible. In collaboration with a metallurgical firm, WHO investigated methods of increasing the carbon content so as to produce the hardest possible steel that would not rust. When this steel was used, metallurgical testing showed that there was no change in the "hardness index" after a bifurcated needle was flamed in a spirit lamp up to 50 times, for 3 seconds on each occasion, but that the index decreased considerably if a needle was flamed for 5 seconds on 25 or more

**Plate 11.14.** Vaccination with the bifurcated needle. The requisite amount of reconstituted vaccine is held between the prongs of the needle and vaccination done by multiple puncture: 15 strokes, at right angles to the skin over the deltoid muscle, in an area about 5 mm in diameter.

occasions. Furthermore, since the major element in the cost of the needles was the amount of steel contained in each, their length was reduced from 65 mm to 50 mm, and they were made somewhat thinner than the original Wyeth needle.

*Durability of needles as modified by WHO.* Field tests were carried out on the durability of the smaller, hardened needles. Working in Egypt, Dr Shafa (Table 11.17) observed the frequency of take rates when a single needle was used for 172 successive revaccinations with a vaccine having a titre of  $10^{8.6}$  pock-forming units per ml. The needle was flamed before

each vaccination by passing it 3 times through the flame of a spirit lamp, and allowed to cool before being dipped into the vaccine vial. Three insertions were performed in each of 172 previously vaccinated individuals; 2 by the scratch method (6–7 mm in length) on one arm, and 1 by multiple puncture (15 strokes within an area 3–5 mm in diameter) on the other arm. The responses were examined on the 6th or 7th day after revaccination. Comparison of the first 86 members of the group with the remainder showed that there were no significant differences in take rates between them but that multiple puncture

Table 11.16. Take rates obtained with the bifurcated needle (multiple puncture) and scratch inoculation

Type of vaccination	Investigator	Country	Vaccination method	Number of subjects observed	Number of major reactions	Take rate (%)
Primary	Ladnyi Shafa	Kenya	Multiple puncture	72	71	98.6
		Egypt	Multiple puncture	105	105	100
	Mayer	Liberia	Linear scratch	105	105	100
			Linear scratch	30	29	96.7
			Multiple puncture	57	57	100
Revaccination	Ladnyi Shafa <sup>a</sup>	Kenya	Multiple puncture	103	58	56.3
			Multiple puncture	117	88	75.2
			Linear scratch	117	77	65.8
			Multiple puncture	158	121	76.6
	Mayer	Liberia	Linear scratch	158	111	70.3
			Linear scratch	551	396	71.9
			Multiple puncture	49	40	81.6
			Multiple puncture			

<sup>a</sup> The same individuals were vaccinated on opposite arms by different methods.

Table 11.17. Comparison of take rates between the first and second half of a series of revaccinations with a single bifurcated needle flamed before each vaccination

Vaccination	First half of group: needle used 1-86 times				Second half of group: needle used 87-172 times			
	Number of vaccinations	Number observed	Number of major reactions	Take rate (%)	Number of vaccinations	Number observed	Number of major reactions	Take rate (%)
First scratch	86	80	43	53.8	86	78	48	61.5
Second scratch	86	80	43	53.8	86	78	53	67.9
Multiple puncture	86	80	58	72.5	86	78	63	80.8

inoculation gave consistently better results than scratch vaccination. Primary vaccinations performed on 93 people, using the same needle, sterilized by boiling, 46 or 47 times, produced takes in all but one person.

*Number of puncture sites.* The amount of vaccinia virus entering the epidermis could be varied by altering either the number of strokes or the number of insertion sites. Both variations were tested. Dr M. A. Rahman, of the Public Health Institute in Dhaka, Bangladesh (personal communication, 1967), showed that, after the revaccination of individuals who had been vaccinated within the previous 3 years, major reactions were somewhat more common after 30 than after 15 strokes, whereas 5 strokes sufficed to produce takes in the great majority of primary vaccinations.

Possibly as a result of the use of low-titre liquid vaccine, there was a long-standing tradition in many countries that the chance of vaccination failure could be reduced by inoculating in 2 sites, especially in revaccination. During the late 1960s several groups of workers studied this problem. Using vaccine that met WHO standards for potency ( $10^8$

pock-forming units per ml) Pattanayak et al. (1970) showed that there was little advantage in using 2 insertion sites (Table 11.18), and that the bifurcated needle was superior to the rotary lancet for both primary vaccination and revaccination.

Lane et al. (1970a) revaccinated 334 subjects using the multiple puncture method with bifurcated needles, 161 of them at a single vaccination site and 173 matched subjects at 2 sites. There was little difference between the 2 groups in take rates, and no significant difference in titres of neutralizing antibody. On the other hand, Nyerges et al. (1973) found that neutralizing antibody titres were somewhat higher after insertions at 2 sites and suggested that immunity might be more persistent after vaccination in this way.

However, there was general agreement that it was much more important to administer a potent vaccine than to use 2 insertion sites or to increase the number of punctures. With the improvements in freeze-dried vaccine, it was a great deal easier to ensure that the vaccine was potent than to change the method of vaccination. To make the technique in the field as simple as possible, the Smallpox

### Use of Bifurcated Needles

WHO procured about 50 million bifurcated needles between 1967 and 1976, of which 5 million are being retained in Geneva together with a smallpox vaccine reserve for emergency purposes (see Chapter 28). The 1970 price of the needles was US\$5 per 1000 needles. The other 45 million needles were distributed during the Intensive Smallpox Eradication Programme to practically all the endemic countries in which WHO-assisted smallpox eradication programmes were operating. Additionally, other countries which wanted to strengthen their vaccination programme or had to deal with smallpox epidemics also received the needles. These countries were Democratic Kampuchea, Lao People's Democratic Republic, Malaysia, the Philippines, Sri Lanka and Viet Nam in the Western Pacific and South-East Asia Regions; Bahrain, Iran, Oman and Saudi Arabia in the Eastern Mediterranean Region, and Argentina, Bolivia, Chile, Colombia, Cuba, Mexico, Peru and Venezuela in the Region of the Americas. If the population of the 31 endemic countries in 1967 is included, the total population of countries in which bifurcated needles were used for vaccination programmes would have been about 2000 million.

Eradication unit recommended a single regimen: 15 strokes with a bifurcated needle at 1 site.

Detailed instructions (SE/68.2 Rev.1) were widely circulated and it was pointed out in them that, with the multiple puncture method, a trace of blood indicated that the punctures were likely to have introduced the virus into the epidermis.

#### *Containers for bifurcated needles*

The package of smallpox vaccine prepared by Wyeth Laboratories contained freeze-dried vaccine, fluid for reconstitution, and bifurcated needles in a disposable plastic container. Disposable appliances were, however, too expensive to be used in the global smallpox eradication programme, and early in

1968, the Smallpox Eradication unit sought a plastic container which would hold about 100 needles, would be cheap to produce and could be sterilized by boiling. The containers eventually used were designed by Dr Shafa, who was successful in stimulating local producers in Bangladesh and Pakistan to produce the container illustrated in Plate 11.15. After the conical end had been unscrewed, needles were placed in the containers with the prongs towards the base, and were sterilized by placing the closed container in boiling water. The bottom of the container was provided with a few holes so that the water could be drained or shaken off after boiling. In the field, needles could be removed aseptically from the container one at a time through the hole at the apex of the conical lid, and placed in an empty container after use, for sterilization next day. These procedures

	Bifurcated needle	61.2	80.6	32

<sup>a</sup> Based on Pattanayak et al. (1970).

**Plate 11.15.** WHO bifurcated needles and plastic containers. The top of one container has been unscrewed so that it can be packed with needles. Holes are provided in the bottom to allow excess water to be removed after sterilization by boiling. Sterile needles are shaken one at a time through the hole in the conical lid.

greatly simplified the vaccinators' work. Subsequently the WHO Regional Office for South-East Asia produced similar containers, and after 1971 they were widely used in all WHO-assisted national smallpox eradication programmes. It is interesting to note that local producers in Bangladesh, India and Pakistan, in which smallpox was endemic, devised a plastic container made of high-density polyethylene which withstood boiling, whereas efforts made by the Smallpox Eradication unit at WHO Headquarters to persuade plastics manufacturers in Switzerland and the USA to produce such containers were unsuccessful.

#### *Packaging and instruction sheets*

Initially the packaging and instruction sheets provided with donated vaccine varied, since they followed the regulations of the donor countries. Usually the multiple pressure or scarification method was described, instructions were given about sterilizing the skin and the numerous and complex contraindications to vaccination were listed.

With the introduction of the bifurcated needle, a simple set of instructions in English and French was included in each box of vaccine. In addition, the contraindications to the use of vaccine in endemic countries were

simplified in accordance with the policy of the Smallpox Eradication unit, as follows: "In endemic smallpox regions or in areas geographically proximate only individuals who are severely ill are not vaccinated." This contraindication was included to avoid vaccination being blamed if the patient died. Later some countries making donations on a bilateral basis—for example, India—prepared their own instruction sheets along the same lines.

As the programme progressed, manufacturers were encouraged to provide the vaccine and the diluent in separate packages, so that only the vaccine needed to be stored in refrigerated space, something that was always in short supply in developing countries.

#### **Jet Injectors**

Jet injectors (trade name Ped-o-Jet) played an important role during the initial phase of the Intensified Smallpox Eradication Programme. They were used to ensure rapid vaccination coverage with satisfactory take rates in national smallpox eradication programmes in Brazil, Zaire, countries in western and central Africa, and to a small extent in several other countries. In all these countries

### Instructions for Smallpox Vaccination with Bifurcated Needle Given in each Box of Vaccine

1. Method for vaccination—multiple puncture technique.
2. Site of vaccination—outer aspect of upper arm over the insertion of deltoid muscle.
3. Preparation of skin—none. If site is obviously dirty, a cloth moistened with water may be used to wipe the site.
4. Withdrawal of vaccine from ampoule. A sterile bifurcated needle (which must be cool if flamed or completely dry if boiled) is inserted into the ampoule of reconstituted vaccine. On withdrawal, a droplet of vaccine sufficient for vaccination is contained within the fork of the needle.
5. Application of vaccine to the skin. The needle is held at a 90° angle (perpendicular) to the skin [see Plate 11.14]. The wrist of the vaccinator rests against the arm. For both primary vaccination and revaccination, 15 up-and-down (perpendicular) strokes of the needle are rapidly made in the area of about 5 mm in diameter. The strokes should be sufficiently vigorous so that a trace of blood appears at the vaccination site. If a trace of blood does not appear, the strokes have not been sufficiently vigorous and the procedure should be repeated. Although it is desirable not to induce frank bleeding, the proportion of successful takes is not reduced if bleeding does occur.
6. No dressing should be used after vaccination.
7. Sterilization of needle may be done by flaming or boiling.
  - (a) Flaming—the needle is passed through the flame of a spirit lamp. It should not remain in the flame for more than three seconds. The needle must be allowed to cool completely before inserting into vaccine ampoule.
  - (b) Boiling—the needle is sterilized by boiling for 20 minutes. Subsequently, the needle must be dried thoroughly to ensure that the fork of the needle does not contain a drop of water when inserted into the vaccine ampoule.
8. Unused, reconstituted freeze-dried vaccine should be discarded at the end of each working day.

bifurcated needles were also used, especially in rural areas and where only small numbers of people required vaccination. In Brazil, the programme was highly organized and there was no shortage of skilled maintenance and repair staff for the jet injectors. In western and central Africa there was a special reason for using the jet injector—namely, the simultaneous programmes of vaccination against smallpox and tuberculosis in Zaire and against smallpox and measles in western Africa. In other areas, in which only smallpox vaccine was being administered, the bifurcated needle, by virtue of its simplicity and advantages in field use, had been universally adopted by 1969 and had replaced jet injectors where these had earlier been used experimentally.

#### History

In immunization campaigns in developed countries, undertaken to control the diseases

of childhood, immunizing antigens other than smallpox vaccine were administered with syringes and needles. At that time, before disposable equipment had been invented, sterilization between vaccinations was time-consuming, but necessary if serum hepatitis was to be avoided. The jet injector overcame this difficulty. It consisted, in essence, of a piston which forced a measured dose of vaccine, under high pressure, through a narrow orifice, thereby achieving subcutaneous inoculation without the need for syringe and needle.

Hingson et al. (1963) had used jet injection to administer local anaesthetics, insulin and various antibiotics since 1947, and after 1954 the procedure had been used on military recruits for the subcutaneous injection of influenzavirus and poliovirus vaccines. By 1962, vaccination against cholera, DPT (diphtheria, pertussis and tetanus), typhoid and yellow fever was being carried out with jet injectors in Central and South America. All

CENTERS FOR DISEASE CONTROL

**Plate 11.16.** The Ped-o-Jet jet injector. **A:** In use in Nigeria. Stepping on the pedal of a hydraulic pump cocked a piston in the "pistol" against a spring and drew in a measured amount of vaccine. The nozzle was placed against the skin and when the trigger was pulled the piston was released forcing a fine high-pressure jet of vaccine into the epidermis. **B:** Assembled in case for transport.

the antigens concerned were introduced subcutaneously by jet pressure, each being given at a different site.

Smallpox vaccination, however, required intradermal deposition of the virus, and in 1962 Dr Aaron Ismach, of the United States Army Research and Development Command, modified the nozzle to enable it to deposit vaccine intradermally (see Millar et al., 1969).

#### *Developmental studies*

In July 1962, Henderson and Dr J. D. Millar, using this nozzle attached to a Ped-o-Jet (Plate 11.16), inoculated 41 previously vaccinated young adults with diluted smallpox vaccine; 32 of them showed satisfactory takes (major reactions). These preliminary results prompted a group of scientists in the Communicable Disease Center (CDC—later the Centers for Disease Control) in the USA to conduct a series of developmental studies on the efficacy and safety of intradermal jet injection for smallpox vaccination. Millar et al. (1969) vaccinated 156 volunteers, of whom 16 were unvaccinated and 140 had been vaccinated more than 5 years before, either with undiluted smallpox vaccine by the multiple pressure technique or with 0.1 ml of various dilutions of smallpox vaccine by jet injector, using the newly developed nozzle. Cutaneous and serological responses in re-vaccinated persons revealed that jet injection of diluted vaccine with a titre of  $10^{6.1}$  pock-forming units per ml<sup>1</sup> was as effective as multiple pressure inoculation of undiluted vaccine ( $10^{7.6}$  pock-forming units per ml). Among the small number of subjects undergoing primary vaccination, jet injection of diluted vaccine with a titre of only  $10^{5.1}$  pock-forming units per ml appeared as effective as multiple pressure inoculation of undiluted vaccine, which suggested that use of the jet injector would result in considerable savings in vaccine. No complications of vaccination, either local (at the inoculation site) or general, occurred in this small series.

Roberto et al. (1969) then conducted studies on cutaneous and serological re-

sponses to primary vaccination in 625 children in Jamaica, comparing the jet injection of diluted smallpox vaccine with multiple pressure inoculation of undiluted vaccine. For jet vaccination with diluted vaccine, the take rate depended on the titre as follows:

Titre (pock-forming units per ml)	Take rate (%)
$10^{6.1}$	≥ 97
$10^{5.4}$	
$10^{5.1}$	90
$10^{4.1}$	62

These results can be compared with the take rate of 96% found in persons vaccinated by multiple pressure with undiluted vaccine ( $10^{7.6}$  pock-forming units per ml). Subjects who developed Jennerian vesicles usually developed neutralizing antibody (2 failures out of 105 subjects). Seroconversion was not found in those who failed to develop such vesicles. Vesicles and scars were generally smaller in the jet-vaccinated subjects than in those vaccinated by the multiple pressure technique. Vaccinal complications did not occur in any of the 625 subjects, and infants tolerated jet vaccination satisfactorily. Roberto et al. (1969) concluded that intradermal jet injection of 0.1 ml of vaccine with a titre of  $10^{5.4}$  pock-forming units per ml or higher was a very effective method of achieving successful primary smallpox vaccination.

These studies showed that intradermal jet injection was satisfactory both for primary vaccination and for the revaccination of individuals who had been vaccinated many years before. Neff et al. (1969) followed up this work with an evaluation of the performance of jet injectors, as compared with the multiple pressure technique, in a well-vaccinated prison population, using serial dilutions of vaccine; they concluded that vaccination by jet injection with a vaccine containing  $10^{6.1}$  pock-forming units per ml was at least as efficacious as vaccination by the standard multiple pressure technique.

Freeze-dried vaccine produced by Wyeth Laboratories was employed in all these studies. As used in the field in western Africa, the vials contained a freeze-dried vaccinia virus suspension which was reconstituted with 10 ml of Hanks' solution, so that 0.1 ml, the volume administered by jet injection, contained at least  $10^{6.5}$  pock-forming units—

<sup>1</sup> Assays of viral infectivity in this study were carried out by titration in primary rhesus monkey kidney cells using half-log dilution steps, and were expressed as TCID<sub>50</sub> per ml. Since viral titres elsewhere in this book are expressed as pock-forming units per ml, the published results have been converted from TCID<sub>50</sub> per ml to pock-forming units per ml, using a factor provided by J.H. Nakano (personal communication, 1982). The tissue culture end-points were about 0.9 log unit higher than the titres on the CA membrane.

considerably more than was required, according to the experimental work.

However, since the improvements in vaccine production procedures, outlined in the earlier part of this chapter, ensured that highly potent vaccine was available, titres in excess of those shown to be necessary in trials were recommended so as to provide a safety margin to allow for the effect of the problems in the handling of vaccine that would inevitably occur in the field at some time or another.

### Application

Provided that the instruments could be properly maintained, jet injection, using the special nozzle for intradermal injection, had obvious attractions for mass smallpox vaccination campaigns. In 1965 Millar and his colleagues in CDC undertook a pilot study of jet injection and multiple pressure vaccination in Brazil, the results of which stimulated that country to undertake a national smallpox eradication programme (Millar et al., 1971). They reported that between 27 January and 15 February 1965, 47 926 residents of Amapá Territory, Brazil, living in both urban and rural areas, were vaccinated, all by jet injection. For purposes of comparison, the traditional multiple pressure method was used in Mazagão, where 34 vaccinators, 2 supervisors and 2 local staff vaccinated 911 persons in 3 hours. In Amapá town, in contrast, 2 jet

vaccinators, 1 recorder and 2 local staff vaccinated 1335 persons in 6 hours (Table 11.19).

Using data obtained in part of this trial and those collected in a conventional mass vaccination campaign in Belém, Millar et al. (1971) analysed the relative costs of the two methods (see Chapter 12, Table 12.5). Jet injection was found to reduce manpower, transport and vaccine requirements and appeared to be more efficient. In urban campaigns it was estimated that jet injection costs were about one-third of those of conventional techniques. They concluded that jet injection, if intelligently applied, could significantly increase the speed, efficacy and efficiency of national mass smallpox vaccination programmes.

CDC launched a smallpox eradication and measles control programme in 20 countries of western and central Africa in 1967, as part of the WHO global smallpox eradication programme (see Chapter 17). The use of the jet injector was regarded as the key to this programme, since it not only reduced the needs for manpower, transport, the quantity of vaccine and the chances of unsuccessful vaccination but also made possible simultaneous vaccination against smallpox and measles. In 1966, when the Director-General of WHO submitted a report to the Nineteenth World Health Assembly on the organization of the global programme, he specifically referred to the usefulness of intradermal jet

### Scars after Vaccination with Jet Injectors

During the Intensified Smallpox Eradication Programme, vaccination scar surveys were often carried out to determine the vaccination coverage of populations. Since the experimental studies with jet vaccination had shown that the resulting lesions and scars were somewhat smaller than those produced by other methods of vaccination, there was some question whether the scars would persist for as long. Dr D. R. Hopkins, of the Communicable Disease Center (CDC) in the USA, studied the persistence of vaccination scars when he was working in Sierra Leone in 1967-1968 and concluded that there was essentially no difference in persistence, whether scars were produced by jet vaccination or by multiple puncture. In 1982, Dr A. Gromyko, while working for the Smallpox Eradication unit, carried out further investigations in Sierra Leone and Côte d'Ivoire and confirmed that, in 80% of subjects, vaccination scars persisted for more than 12 years.

injection for vaccination when large groups could be assembled. WHO provided some 100 jet injectors to the national programmes in Pakistan, the Sudan and Zaire in 1967 and 1968. Some 10 jet injectors were also kept in the Regional Offices for the Eastern Mediterranean, Africa and South-East Asia and in the Smallpox Eradication unit, for emergency use. However, largely because of problems with their maintenance and repair, they were little used except in Brazil, western Africa and Zaire, and briefly in India and Indonesia.

#### *Vaccine for jet injectors*

The vaccine to be used in jet injectors had to meet special requirements, relating both to bacteriological sterility and to potency. Because the vaccine was administered parenterally, it was essential that it should have a low to nil bacterial count when tested in the laboratory. This recognized the fact that bacterial sterility could not be achieved unless the vaccine was produced in eggs or tissue culture (see box opposite), and no laboratories at that time produced such a vaccine which met other WHO standards of potency and heat stability. Although the vaccine had inevitably contained a few non-pathogenic bacteria, no unusual complications due to bacterial infection had been observed during the extensive field trials of the jet injector. As a working standard, a WHO Scientific Group on Smallpox Eradication (1968) noted that vaccine containing up to 5 non-pathogenic bacteria per ml had been extensively used for jet injection without untoward effects.

In the smallpox eradication programmes

carried out with United States assistance in 20 countries of western and central Africa, freeze-dried calf lymph vaccine produced by Wyeth Laboratories was used. Low or zero bacterial counts per ml were achieved with this vaccine by frequent and meticulous cleansing of the animal skin from the time of inoculation to that of harvest. Producers in Switzerland and the USSR were likewise successful, as were some others, in providing a vaccine of low bacterial content, and this vaccine was used in Zaire. For Brazil, the vaccine was produced in Brazilian laboratories, and although many batches of the vaccine contained more than 5 non-pathogenic bacteria per ml, and sometimes some pathogenic bacteria, no adverse consequences were detected during the eradication programme in Brazil.

The other feature of the vaccine used for jet injection was that the recommended titre of the reconstituted vaccine was lower than that required for multiple pressure vaccination—namely,  $10^{6.5}$  instead of  $10^{8.0}$  pock-forming units per ml—since all the virus in the injected dose was introduced into the skin, rather than a minute fraction as in the multiple puncture method. Wyeth Laboratories produced a special vaccine vial which, when reconstituted with 50 ml of saline (a quantity sufficient to vaccinate 500 persons), gave this titre. When other vaccines were used, a dilution factor was chosen to give the same final concentration. For example, the vial used for vaccine produced in the USSR contained the freeze-dried residue of 0.2 ml of vaccine with a minimum concentration of vaccinia virus of  $10^8$  pock-forming units per ml. One ampoule of this vaccine diluted with

### Bacterial Counts of Vaccine Used in Jet Injectors

Bacteriologically sterile smallpox vaccine can be produced on the CA membrane or in cultured cells. However, the vast majority of producers used animal skin, and the resulting vaccine always contained some bacteria. The number of viable bacteria could be reduced by treatment with phenol, but it was impossible to produce bacteriologically sterile vaccine which remained potent in terms of its viral content. The term "bacterial count zero" (see Table 11.7) does not mean "bacteriologically sterile" but only that no viable bacteria were found in the samples tested.

A conflict arose in the framing of standards for vaccine for use in jet injectors because of the insistence by experts on biological standardization that all vaccine designated for parenteral use in man should be bacteriologically sterile and the pragmatic view expressed by the WHO Scientific Group on Smallpox Eradication (1968) that freeze-dried vaccine containing up to 5 non-pathogenic bacteria per ml of reconstituted vaccine had been used for jet injectors in recent extensive trials without untoward effects. In fact, no new standards were drawn up by WHO. However, in 1969 the United States health administration proposed that the vaccine for jet injectors should pass the same sterility test as that used for other vaccines for parenteral use (*Federal Register*, 1969). At that time Wyeth Laboratories were supplying the jet injector vaccine, and although the bacterial count was often zero it was not bacteriologically sterile. Hence the concern of Dr J. H. Brown of Wyeth Laboratories, Henderson of WHO, and Dr D. Millar of CDC, all of whom believed that the requirement was academic and would hamper the progress of the eradication campaign in western Africa, sponsored by the USA, where jet injectors were a major tool. Discussions took place with the United States health administration and eventually the requirement was not imposed.

about 6.6 ml of saline therefore gave a final concentration of about  $10^{6.5}$  pock-forming units per ml. However, since in practice the vaccine had a virus concentration of 2 or  $3 \times 10^8$  pock-forming units per ml, the vaccine in 2 ampoules was usually diluted with 25 ml of saline (a lot size easily available on the market) for intradermal jet injection. In places in which the Wyeth vaccine and the corresponding diluent were not available, WHO provided national eradication programmes with special vials containing 25 ml of saline together with instructions for dilution. Sometimes, by mistake, distilled water was used to reconstitute the freeze-dried vaccine. Vaccine so reconstituted caused a sharp pain when injected, which was not the case when saline was used as the suspending fluid, but it proved satisfactory otherwise.

Manuals in English, French and Portuguese, describing the maintenance and repair of jet injectors, were developed by the Communicable Disease Center and produced for national vaccination campaigns in which this instrument was used.

### *Discontinuation of use of jet injectors*

A few disadvantages of jet injectors emerged during the campaigns in which they were used. In contrast to the simplicity of bifurcated needles, the jet injector required meticulous care and maintenance and considerable repair skills, which could not always be provided despite all the efforts to prepare a detailed, profusely illustrated manual. Furthermore, the instrument was expensive and heavy. With the introduction of bifurcated needles in 1968, it became apparent that these were far more functional, and in well-organized campaigns it was found that individual vaccinators could vaccinate 1000–1500 persons per day. At the same time, experience with jet injectors showed that vaccination teams were seldom able to assemble more than 2000–3000 persons per day, on average, hence the jet injectors offered little advantage. Thus their use was largely confined to the programmes begun in 1967–1968—in Brazil, countries of western and central Africa, and Zaire.

### *Other jet injectors*

In 1968 and 1969, Arita coordinated investigations of several other devices developed by various manufacturers: the Press-o-Jet, a hand-operated jet injector produced in the USA, the Dermojet (modified as the Vaccijet) produced in France, and the Porton needleless injector produced in the United Kingdom. Some experimental models were sent to Kenya and their suitability was tested in the field by Ladnyi. None of these instruments proved as satisfactory as the better-established Ped-o-Jet with regard to take rates, mechanical reliability or general convenience. By 1969, the advantages of the bifurcated needle had been fully recognized, and the studies were discontinued.

## MODIFICATION TO VACCINATION PROCEDURES

### Preparation of Skin

The principal modification to previously used procedures related to the cleansing of the skin prior to vaccination. It was generally believed that bacteria on the surface of the skin might cause infection if introduced during vaccination. For smallpox vaccination it was usual to cleanse the skin with acetone or 70% alcohol. With the latter, such cleansing, to be effective, had to continue for about 15 seconds, although even then there was no assurance that the skin would be free of spore-forming bacteria. However, if vaccine was deposited on the skin before it was completely dry, the potency could be reduced by the residual alcohol.

According to the *Memorandum on Vaccination against Smallpox* (England and Wales, Ministry of Health, 1962), "Many doctors use nothing at all if the arm is reasonably clean, and there is no evidence to condemn this practice". Subsequently, Dann (1966) reported that, when 1078 intradermal, subcutaneous, intramuscular and intravenous injections were done without preparation of the skin, there was no subsequent infection. He concluded that "at best, then, pre-injection skin preparation reduces the risk of infection and probably in practice it has no useful effect whatsoever". The *Handbook for Smallpox Eradication Programmes in Endemic Areas* (SE/67.5 Rev.1) stated that no pretreatment of the skin was necessary for vaccination but that, if the site was obviously dirty, the skin

should be wiped with a cloth moistened with water. This minor change from the traditional method greatly facilitated vaccination programmes, since it dispensed with the need for additional material such as cotton swabs and antiseptics and speeded up the operation. It was subsequently discovered that, in the smallpox eradication programme in Iran in 1953-1961, glycerolated lymph had been administered by the scratch method to over 30 million persons in whom the site was not cleansed, since the use of alcohol and even soap was not recommended for fear of inactivating the virus: no serious local infections were reported (WHO/SE/78.120).

### Neonatal Vaccination

As has been noted in Chapter 7, in the early 1960s Rao had introduced the practice of neonatal vaccination in hospitals, first in Madras and subsequently throughout urban areas in south India. The WHO Expert Committee on Smallpox (1964) recommended that in endemic areas primary vaccination should be carried out as early as possible, preferably in the neonatal period, and repeated about 12 months later. This view was reinforced in 1967 (WHO Scientific Group on Smallpox Eradication, 1968) and again in 1971 (WHO Expert Committee on Smallpox Eradication, 1972).

During the intensified eradication programme in India, neonatal vaccination was widely practised in municipalities and corporations, where the majority of births occurred in health institutions and maternity centres whose staff were provided with vaccine and bifurcated needles and trained in their use. Similar procedures were adopted in certain African countries, where births occurred in health institutions or were assisted by experienced midwives. However, in the rural areas of the Indian subcontinent and in most parts of Africa, neonatal vaccination was not possible, and efforts were therefore made to vaccinate infants at the first health examination, where such facilities existed.

## THE SEARCH FOR NEW VACCINES

As has been mentioned earlier in this chapter, at the outset of the Intensified Smallpox Eradication Programme in 1967 the Smallpox Eradication unit reached the

conclusion that smallpox could be eradicated by the effective use of the vaccine then available. Not only did it see no need for a new vaccine but it also feared that the trials that such a product would have to undergo would act as a brake on the global eradication programme. Since, despite the tremendous amount of work involved in coordinating this programme, the unit at its largest consisted of only 6 professional and 4 supporting staff, extremely careful attention had to be given to the determination of priorities.

However, advanced industrial nations which had eliminated smallpox decades earlier saw the problem from a different perspective. Health officials and the public alike were concerned by the sickness, occasional complications and, rarely, death that followed the administration of existing smallpox vaccines. Virology had advanced a long way since 1798, when vaccination had first been introduced, and many workers, especially in Europe, Japan and the USA, sought a vaccine that would be associated with milder lesions after primary vaccination and especially with less likelihood of complications.

Methods of improving smallpox vaccine, from the point of view of reducing complications, were extensively discussed; first, in 1969, at a symposium on smallpox organized in Zagreb by the Yugoslav Academy of Sciences and Arts, (Gušić, 1969) and again in 1972, when a special session on smallpox vaccination was convened in Bilthoven by the International Association of Biological Standardization (Regamey & Cohen, 1973). Three approaches were adopted in the studies designed to develop less reactogenic vaccines: (1) selection of the least reactogenic strains from among those currently being used for vaccine production; (2) development of an attenuated strain; and (3) use of inactivated vaccine. The second and third approaches included attempts to develop a method in which attenuated or inactivated vaccine was first used to provide an initial immunological stimulus and thus partial protection, followed by vaccination with the usual smallpox vaccine, a procedure which should in theory reduce complications. A fourth series of investigations, largely independent of the issue of vaccinal complications, was aimed at developing a tissue culture vaccine which, unlike vaccine of animal skin origin, would be sterile. None of these attempts resulted in an alternative vaccine which could be widely used for the

global smallpox eradication programme. Nevertheless, the efforts of laboratory investigators and epidemiologists in these once important research activities are significant for the historical record. If attempts to immunize human beings against a variety of diseases by the incorporation of designated foreign genes in vaccinia virus are successful, there will be renewed interest in methods of reducing the incidence of severe complications.

### **Selection of Vaccinia Virus Strains of Low Pathogenicity**

Polak et al. (1963) reported on the pathogenicity to man of vaccines made with the Bern, Copenhagen, Ecuador and Lister strains of vaccinia virus. The generalized responses, in terms of the degree of morbidity (the ratio of number of bed-patients to number of successful vaccinations), high fever, and prolonged fever in bed-patients, were recorded. The Lister strain produced the mildest response, followed by the Ecuador strain. The Copenhagen and Bern strains were similar in their effects and of greater pathogenicity than the other two. Thus, when a sound evaluation method was used with adequate controls, it was demonstrated that vaccinia strains differed in their pathogenicity to man. In addition, the study suggested that the potency of the vaccine (in terms of its titre) seemed to have no bearing on the course of illness following vaccination. These results supported the views held by many epidemiologists that different strains of vaccinia virus were associated with different frequencies of complications (see Chapter 7). For example, the Bern strain, once used in Austria, Germany, Switzerland and Yugoslavia, had been associated with much higher complication rates (especially of postvaccinal encephalitis) than those reported in the United Kingdom (in which the Lister strain was used) or the USA (in which the New York City Board of Health strain was used). By 1971, these countries, with the exception of Yugoslavia, had changed to the Lister strain for vaccine production, and from that time on the complication rates decreased.

In the 1960s, Dr Marennikova and her colleagues in Moscow collected vaccinia strains from different vaccine producers and studied their pathogenicity, as determined by inoculation by various routes into rabbits, mice and irradiated rats. Table 11.20 sum-

### Vaccinia Virus Strains

It is impossible to review comprehensively the origin and nature of the various vaccinia virus strains which have been used by laboratories since early in this century. Of 35 strains, many of which were used only for laboratory studies and not for vaccination, whose origin had been investigated by Wokatsch (1972), 7 were said to have been derived from variola virus: Dairen (Japan), Ikeda (Japan), Lister (United Kingdom), LMC (United Kingdom), Tashkent (USSR), Temple of Heaven (China) and Williamsport (USA). However, all early experiments on the adaptation of variola virus to growth in calves were done in vaccine production laboratories. Restriction endonuclease analyses of variola and vaccinia DNAs, and the negative results of Herrlich et al. (1963), whose experiments were conducted in premises in which vaccinia virus had never been used, suggest that the so-called transformation of variola virus into vaccinia virus was due to contamination.

Four strains—namely, EM-63, Lister, New York City Board of Health, and Temple of Heaven—were the strains most widely used for vaccination, and have been inoculated into perhaps one-third of the population of the world since 1950. It is of interest to examine their histories.

The EM-63 strain was widely used in the USSR and between 1967 and 1970 was the strain used for vaccine donated to the WHO Intensified Smallpox Eradication Programme and in many bilateral aid programmes. It was received in Moscow in 1963 from Ecuador via Denmark, where it had been passaged in rabbits and calves. The Ecuador strain was in turn derived in 1940 from the strain used by the Massachusetts Department of Health, Boston, USA (Edsall, 1973), where it had been used for many years for the production of a vaccine with a long history of innocuity. It appears to have originated from the New York City Board of Health strain.

The Lister strain was said to have been isolated in the Vaccine Institute in Cologne, Germany, from a Prussian soldier suffering from smallpox in the Franco-Prussian war in 1870. It probably arose as a result of contamination with the Institute's own vaccine strain (Wokatsch, 1972; C. Kaplan, personal communication, 1982). The strain has been used in the United Kingdom since 1892 and at the Lister Institute since 1916. It was passaged through man initially, then rabbit and sheep skin in alternation. It was used in the development of the International Reference Preparation of Smallpox Vaccine established in 1962. After transfer to other laboratories it was also called the Liverpool, Mérieux 37 and Nigeria strains. A derivative of the Lister strain (L-IVP) was used for the production in the USSR after 1971 of most of the vaccine donated to the Intensified Smallpox Eradication Programme.

The New York City Board of Health strain appears to have had a somewhat lower pathogenicity, in terms of the frequency of complications, than any other widely used vaccinia strain. According to the American Type Culture Collection, the New York City Department of Health Laboratories started manufacture of smallpox vaccine in 1876 with seed virus supplied by Dr J. Loines, who brought it over from England in 1856. This strain was distributed to many other laboratories, where it acquired different names, such as IHD, LED-O, Noguchi, WR and Wyeth, and different biological properties if it was passaged in different ways, especially if intratesticular or intracerebral injection of rabbits was employed.

The Temple of Heaven strain was used for the smallpox eradication programme in China. In 1926, pus from a smallpox patient was passed 3 times in monkeys, then 5 times in rabbits (skin/testes), 3 times in calf skin, 1–2 times in rabbit skin and a further 1–3 times in calf skin. Contamination with vaccinia virus probably occurred during these passages.

Table 11.20. Classification of strains by degree of pathogenicity<sup>a</sup>

Country of origin	Strain
<b>High pathogenicity</b>	
China	Temple of Heaven
Denmark	Copenhagen
France	Paris
Hungary	Budapest
Japan	Dairen, Ikeda
USSR	Gam, MRIVP, Per, Tashkent, TBK, Tom
<b>Moderate pathogenicity</b>	
Federal Republic of Germany	Bern
India	Patwadangar
USSR	BIEM, B-15
United Kingdom	Lister
<b>Low pathogenicity</b>	
USSR	EM-63
USA	New York City Board of Health

<sup>a</sup> Based on Marennikova et al. (1969).

marizes the results obtained for a number of different strains (Marennikova et al., 1969). Subsequent investigations (Marennikova, 1973) showed that the Tashkent strain was associated with much higher levels of reported postvaccinal complications (46 cases per million doses distributed, with 18 per million of encephalitis) than the B-51 or especially the EM-63 strain (17 per million doses with 7 per million cases of encephalitis for EM-63). Likewise, the Wyeth (New York City Board of Health) strain, of low pathogenicity for experimental animals, was associated with a relatively low rate of postvaccinal complications (see Chapter 7).

This work, which was presented at two major conferences of vaccine producers, influenced health authorities' decisions as to the choice of a strain, particularly as additional epidemiological data became available. For example, the Tashkent strain, which according to Dr Marennikova was highly pathogenic for animals, had been used in the USSR for the production of smallpox vaccine for local use and for donation to India and other Asian countries up to 1966. It caused considerable concern among Indian health workers because of the severe local reactions (Goyal et al., 1969), and after 1966 its production was discontinued in the USSR.

Table 11.21, based on data from WHO surveys in 1968 and 1971, shows how vaccine producers in several countries changed from the strains they had previously been using to the less reactogenic Lister strain, which was

distributed by the WHO International Reference Centre both as a reference vaccine for potency assays and as seed lots for vaccine production. Of 71 vaccine producers in 49 countries or areas, 42 (59%) were using the Lister strain in 1971 compared with 22 (31%) in 1968.

In Japan, complications of smallpox vaccination caused substantial public concern in the early 1970s and the health authorities re-evaluated their traditional Ikeda vaccinia strain in comparison with the Lister strain. Country-wide studies of vaccinal reactions, such as fever, the size of lesions, and the need for hospitalization, showed that the Lister strain was less reactogenic, and all 6 Japanese production laboratories changed to it in 1971.

### Attenuated Strains

In 1931, Dr T. M. Rivers of the Rockefeller Institute of Medical Research, New York, initiated a series of passages of the New York City Board of Health strain of vaccinia virus through minced chick embryo cells, primarily in order to obtain a bacteria-free vaccine (Rivers, 1931). Passage in rabbit testes was included, initially to obtain a bacteria-free preparation for passage in tissue culture and later to restore the pathogenicity of the virus for rabbit skin. In the process, the virulence of the virus became attenuated.

Two strains were used in subsequent studies; their passage history has been summarized by Barker (1969). Strain CVI-78 had been passed 124 times in chick embryo explants and 19 times on the CA membrane; strain CVII had been carried for a total of 235 passages in chick embryo explants. Rivers & Ward (1935) showed that CVII was suitable for human vaccination by intradermal inoculation. Noting that this tissue culture vaccine consistently produced less severe reactions in rabbits and humans than did the New York City Board of Health calf lymph vaccine, Rivers et al. (1939) carried out further tests, which showed that primary vaccination by intradermal injection of the high-passage tissue culture virus produced only red papular lesions; pustules did not develop and there were few constitutional symptoms. However, they believed that such vaccination would not give complete protection against smallpox, and they recommended that revaccination with the calf lymph vaccine should be carried out 6 months to 1 year later to produce solid and lasting immunity.

<sup>a</sup> Based on data from WHO surveys.

The Rivers strains attracted the attention of Dr C. H. Kempe, of the University of Colorado Medical Center, Denver, USA, who was interested in the use of a less reactogenic vaccine in order to reduce the severity of reactions in children suffering from eczema or with other contraindications to vaccination. Using CVI-78, Kempe et al. (1968) vaccinated 1009 patients suffering from eczema (879 primary vaccinations; 130 revaccinations), 326 by the multiple pressure method and the rest by subcutaneous inoculation of graded doses. Local reactions and temperature elevations were much milder than those seen in children vaccinated with standard vaccine and, except for 2 cases of mild erythema multiforme, no patients suffered from virus dissemination or other complications. The mean neutralizing antibody titre of 162 subjects given primary vaccination with CVI-78 by multiple pressure was very similar to that obtained in 45 controls vaccinated with calf lymph vaccine.

Vaccine produced on the CA membrane from the CVII strain of Rivers was used over a period of 5 years for the primary vaccination of more than 60 000 army recruits in the Netherlands to evaluate whether such a strain would reduce complications, as compared with the conventional calf lymph vaccine, which at that time was produced with the Lister strain (Noordaa et al., 1967). All of the recruits received, in addition, 2 ml of vaccinia-immune globulin. The local reaction after primary vaccination with the CVII strain was milder than that with other vaccines and there was only 1 mild case of postvaccinal encephalitis in the 60 000 vaccinations, but the neutralizing antibody titres measured a year after vaccination were also somewhat lower than usual. The research workers in the Netherlands concluded that the use of the CVII strain would probably reduce complications, but that, to produce sufficient protection against smallpox, it should be followed by revaccination with standard calf lymph vaccine 12 months later.

Tint (1973) summarized experience with primary vaccination with the CVI-78 strain in 9000 subjects (3500 of whom had eczema or other skin diseases) in England, Japan and the USA. He suggested that vaccination with this attenuated strain on its own was probably not sufficient to provide protection against smallpox, but that its use in eczematous children as a preliminary to vaccination with standard vaccine would substantially lower the risks of

eczema vaccinatum. Such a regimen might be feasible in industrialized countries, but clearly a two-step schedule was out of the question for vaccination in the global smallpox eradication programme.

Because of increasing concern about the morbidity and mortality associated with smallpox vaccination, the National Institute of Allergy and Infectious Diseases, National Institutes of Health, USA, sponsored a study of the reactogenicity and immunogenicity of 4 vaccines: calf lymph and egg vaccine made from the New York City Board of Health strain, egg vaccine made from CVI-78, and Lister sheep vaccine, administered at several dosages by percutaneous and subcutaneous routes (Galasso, 1970). The results were published in 1977 in 6 papers in the *Journal of infectious diseases*. Primary vaccination by the subcutaneous route, while accompanied by lower rates of fever, led to unsatisfactorily low antibody responses both initially and after standard percutaneous revaccination (Galasso et al., 1977). In a comparison of the 4 vaccines, it was concluded that:

"For percutaneous primary vaccination the CV-I strain was 10-fold less infectious than the other three vaccines. CV-I also differed from the other three vaccines in that it produced smaller skin lesions and vaccination was not associated with a febrile response. Only 30% of recipients of primary percutaneous CV-I vaccination with primary type skin responses developed neutralizing antibody; in contrast neutralizing antibody occurred in 82%–85% of the recipients of the other three vaccines.

"After standard challenge vaccination, those children with previous successful percutaneous CV-I vaccination were more likely to have a primary-type skin response. CV-I vaccinees also tended to have larger skin lesions after revaccination, but fever and minor complications were not more frequent. One month after revaccination, neutralizing antibody was present in 93%–96% of those with "takes" on primary vaccination with NYC-CL, NYC-CAM, or Lister vaccines, in contrast to only 75% in CV-I vaccinees."

Thus the Rivers attenuated strains, which had been studied most extensively (Galasso et al., 1977), appeared to be insufficiently immunogenic for use in vaccination against smallpox.

Workers in several other countries developed attenuated vaccines during the 1970s, since it was believed at that time that smallpox vaccination would have to be maintained for many years after eradication and

that an attenuated vaccine would then be necessary. In the Federal Republic of Germany, Stickl and his collaborators (Hochstein-Mintzel et al., 1975) produced a highly attenuated strain of vaccinia virus (MVA) by 572 serial passages of the Ankara strain in chick embryo fibroblasts. In the process, the molecular weight of the viral DNA was diminished by 9% and the strain was shown to have greatly reduced virulence for the chick embryo, laboratory animals and man (Mayr et al., 1978), but its immunogenicity was never adequately tested. Stickl et al. (1974) proposed that it should be used: (1) routinely as pre-immunization for primary vaccinations, when it should be followed by conventional vaccine; and (2) for both primary vaccination and revaccination of all individuals at special risk (e.g., with eczema or under immunosuppression). Its probable safety in immunosuppressed individuals was suggested by experiments in irradiated rabbits reported by Werner et al. (1980).

In Japan, Tagaya et al. (1961) recovered an attenuated strain (DIs) from the standard Japanese vaccine strain Dairen by passage in 1-day-old chick embryos. It produced very small pocks on the CA membrane and was not pathogenic for mice, guinea-pigs or rabbits, but produced small skin lesions and induced antibody production after scarification of the skin of cynomolgus monkeys. The immunity produced in rabbits was poor but antibody levels in monkeys were similar to those produced by the parent strain (Kitamura et al., 1967). Tagaya et al. (1973) concluded that DIs was not suitable for use as a smallpox vaccine, but it might have a role if "prevaccination" became an accepted practice.

Stimulated by Tagaya's results, Hashizume (1975) deliberately sought attenuated variants of the Lister strain by serial passage in

rabbit kidney cells at 30 °C and subsequent selection of a small pock from the CA membrane. The variant most extensively studied, LC16m8, was much less pathogenic after intracerebral inoculation in monkeys than CVI, EM-63, Lister or the New York City Board of Health strains (Hashizume et al., 1973), but produced a satisfactory immune response (haemagglutinin-inhibiting and neutralizing antibody) in humans as well as in vaccinated animals (Hashizume, 1975).

In 1974 the Smallpox Vaccine Committee, Ministry of Health, Tokyo, organized a large-scale field evaluation of a number of vaccines, including one produced in rabbit kidney cells with the LC16m8 strain, more than 40 000 persons being vaccinated (Japan, Ministry of Health, 1975). There were no notifiable severe complications among these subjects, those receiving LC16m8 vaccine being closely followed. While the take rates with the LC16m8 vaccine were not significantly different from those of the other vaccines tested, the fewest general responses and smallest local responses were obtained with this vaccine (Table 11.22). Among those receiving LC16m8 vaccine, 1 case of eczema vaccinatum, 3 cases of convulsions and 8 cases of generalized vaccinia were discovered, all of which were mild. It was not clear whether the 3 cases of convulsions were related to the vaccine. The examination of 142 vaccinated subjects by electroencephalography showed that the number of temporary anomalies was lowest in those vaccinated with the LC16m8 vaccine (Table 11.23).

Tests for immunogenicity were carried out in 138 persons vaccinated with LC16m8 vaccine by challenging them with Lister vaccine 12 months later. Major reactions were seen in 18.8%, a rate similar to that observed in 714 persons vaccinated with the Ikeda strain, and challenged with that strain a year

Table 11.22. Results of large-scale study (Japan, 1974) of response to various vaccines<sup>a</sup>

Strain	Year of investigation	Number of subjects	Take rate (%)	Average diameter of induration (mm)	Proportion with fever (> 37.5 °C) (%)
LC16m8	1973-1974	10 578	95.1	6.1	7.7
Ikeda <sup>b</sup>	1968-1970	1 506	99.1	18.2	25.0
EM63	1969-1970	1 846	c	17.4	21.3

later. Thus it appeared that the immunogenicity of the LC16m8 vaccine was similar to that of other vaccines. Although no field experience was available to provide evidence of the protective effect of this vaccine against smallpox, freeze-dried LC16m8 strain virus grown in rabbit kidney cells is being held as part of a reserve stock of vaccine in Japan. Because of its low reactogenicity and because it can be produced in tissue culture, the LC16m8 strain might be a good candidate for use as a vector for other antigens should this procedure become a practical proposition. The average loss of titre of this vaccine after 4 weeks at 37 °C was estimated to be about 10<sup>0.4</sup> pock-forming units per ml, which is comparable to that of calf lymph vaccine of acceptable heat stability (T. Kitamura, personal communication, 1984).

In 1970 workers in China produced an attenuated variant (G-9) of the Temple of Heaven strain by inoculating children with plaque-purified material and selecting from among those reacting with small skin lesions. The strain produced smaller pocks than the parental strain on the CA membrane and has been used experimentally for the primary vaccination of several million children, but no reports on its immunogenicity or of complications following its use are available.

### Inactivated Vaccines

Prior to 1960 only a few live vaccines were available—namely, those for smallpox, tuberculosis and yellow fever—whereas many vaccines consisted of inactivated antigens—pertussis, typhoid, cholera, diphtheria toxoid,

tetanus toxoid, etc. Although there are theoretical reasons, discussed in Chapter 3, why inactivated vaccinia virus vaccines, without a follow-up with live virus vaccine, are unlikely to be effective, several research workers undertook developmental studies of inactivated smallpox vaccine in the hope that it might reduce the complications of vaccination.

The earliest study was that reported by Janson (1891), who found that subcutaneous injections of heat-killed vaccine gave equivocal results in children. Many other methods of inactivation were employed (Kaplan, 1962, 1969; Turner et al., 1970) including the use of formaldehyde, ultraviolet irradiation and photodynamic inactivation. Although some of the resulting inactivated vaccines produced neutralizing antibodies in rabbits, none was satisfactory for the primary vaccination of human subjects.

Because complications, especially post-vaccinal encephalitis, were very much less common after revaccination than after primary vaccination, several attempts were made to "pre-immunize" subjects with inactivated virus, before inoculation with standard vaccine 1–2 weeks later. Herrlich (1959, 1964) prepared an inactivated vaccine by treatment with formaldehyde, which was used on a small scale in the Federal Republic of Germany and in the German Democratic Republic from the late 1950s as a form of pre-immunization designed to reduce the risk of vaccinal complications. The procedure was to use inactivated "vaccinia-antigen" first and then, 2–3 weeks later, to give conventional live virus vaccine as a booster. In some cases in which pre-immunization was used, the second vaccination produced a large swollen area of erythema and induration surrounding the site of inoculation. In any case, the procedure did not completely eliminate complications. "Vaccinia-antigen" plus vaccinia-immune gamma-globulin, but without follow-up live virus vaccine, was given to 2 elderly patients involved in the Meschede outbreak of smallpox (see Chapter 4) 10–14 days before their exposure, but did not protect either from smallpox, from which one of them died (Wehrle et al., 1970).

A two-step procedure, using gamma-irradiated vaccine for the priming dose, was carried out in a field trial in eastern Europe in 1977 (Marennikova et al., 1978c). One case of postvaccinal encephalitis occurred in a child with congenital macrocephaly, among some

23 000 vaccinated subjects, all of whom were over 3 years of age (S. S. Marennikova, personal communication, 1985).

### **Production of Vaccine in Eggs and Tissue Culture**

#### *Vaccine production on the CA membrane*

Soon after the demonstration by Goodpasture et al. (1932) that vaccinia virus would grow on the CA membrane, Goodpasture & Buddingh (1935) published a detailed analysis of the suitability of eggs for the large-scale production of vaccine. The advantages were that production methods were relatively simple and that bacteriologically sterile vaccine could be obtained. Glycerolated egg vaccines were in use in the state of Texas, USA, from 1948 (Cook et al., 1953) and in New Zealand and Sweden from the 1960s.

Freeze-dried vaccine derived from the CA membrane was produced on an experimental scale by Jackson et al. (1956) and on a commercial scale in Sweden (Hedström, 1970). Freeze-dried vaccine prepared on the CA membrane largely replaced calf skin vaccine in Brazil in 1958 (Claussell, 1963) and was used on a very large scale throughout the smallpox eradication programme in Brazil (Voegeli, 1973). Unfortunately, many batches of the Brazilian vaccine did not meet WHO standards for heat stability (see Chapter 12).

Although there has been no evidence of complications or adverse effects caused by avian leukosis viruses in the millions of subjects vaccinated against yellow fever with virus grown in eggs, these agents became a matter for concern when, in about 1967, it was discovered that they were commonly present in eggs. Early in 1970 Swedish producers changed to eggs from flocks free from avian leukosis for smallpox vaccine production.

#### *Vaccine production in cultured cells*

As has already been described in relation to the development of the CVI and CVII strains of attenuated vaccinia virus, production in cultured cells began even earlier than in eggs (Rivers, 1931). Over the next 3 decades efforts were made periodically to produce vaccine in cultured cells, at first from chick embryos and later in cell monolayers derived from a variety of sources. However, as with egg vaccine, tissue culture vaccine was not widely adopted, mainly because production in animal skin was simple and cheap and yielded a vaccine that was heat-stable when freeze-dried and was known to protect against smallpox. Furthermore, the seed lot virus system had not been well established when cultured cells first became available for the commercial production of smallpox vaccine,

### **Avian Leukosis and Egg Vaccine**

The WHO requirement for smallpox vaccine from chick embryos (revised in 1965; WHO Expert Group on Requirements for Biological Substances, 1966) indicated that "only eggs from flocks known to be free from disease, including avian leukosis, shall be used". In 1967 a Swedish laboratory proposed to donate egg vaccine to WHO. The vaccine was sterile and thus suitable for jet injector use, but it was produced from flocks which had not been tested for avian leukosis, whose pathogenicity for man was then unknown. In Sweden, egg vaccine had been used for a long time, and Espmark (1969) reported that there had been no increase in leukaemia in the population. Yellow fever vaccine was also being produced in eggs from untested flocks. Despite arguments advanced by Dr Holger Lundbeck, Director of the National Bacteriological Laboratory, Sweden, and by Henderson, the Chief of the Biological Standardization unit of WHO did not agree to accept the donation from Sweden. The Swedish laboratory finally produced a vaccine from leukosis-free flocks and donated vaccine to WHO. However, in Brazil, smallpox vaccine from eggs produced from flocks which had not been tested for avian leukosis, but were almost certainly carriers of the virus, was used throughout the eradication programme, with no known ill effects.

and it was feared that serial passage of vaccinia virus in tissue culture might lead to its attenuation. After 1967, when the Intensified Smallpox Eradication Programme was initiated, WHO did not promote the production of vaccine in cultured cells because it was realized that the success of the eradication campaign was heavily dependent on the production of large amounts of vaccine in laboratories in developing countries, which were unlikely at that time to be able successfully to produce tissue culture vaccine.

In the late 1960s, the WHO International Reference Centre for Smallpox Vaccine initiated a development study with Lister vaccine grown in primary rabbit kidney cells. At the time this was the only tissue culture vaccine comparable with conventional calf lymph vaccine in terms of heat stability, immunogenicity and reactogenicity (Hekker et al., 1973a). The production method was simple and cheap, the vaccine was sterile and free from mycoplasmas and other adventitious agents, and it maintained its potency for up to 8 weeks at 37 °C. The actual reductions in titre, ranging from  $10^{0.2}$  to  $10^{0.4}$  pock-forming units per ml after 8 weeks at 37 °C, were smaller than those of the calf lymph vaccine tested as a control. The immunogenicity of this vaccine was tested by measuring the neutralizing antibody titres in subjects 1 year after primary vaccination, a control group having been vaccinated with conventional calf lymph vaccine. All the subjects produced neutralizing antibody and there was no significant difference in the results obtained, as between tissue culture and calf lymph vaccines. (Hekker et al., 1973b). Measurement of the antibody titre 2 months after revaccination with the tissue culture

vaccine showed an adequate booster effect compared with the calf lymph control group.

Because of these successful results, a field trial on a large scale in Lombok, Indonesia, was jointly organized in 1973 by the Smallpox Eradication unit, the WHO Regional Office for South-East Asia and the government of Indonesia. A total of 45 443 children under the age of 15 years were vaccinated with tissue culture vaccine and the results compared with those for 9061 children of a similar age and sex distribution who had been vaccinated with the standard Lister strain calf lymph vaccine (Hekker et al., 1976). The success rate with tissue culture vaccine reached 97% in primary vaccination and 75% in revaccination (Table 11.24), results comparable with those obtained with the calf lymph vaccine.

The children were carefully followed up for vaccination complications. The only suspected complication was a fatal case of possible encephalitis in a 5-month-old girl who had been vaccinated with tissue culture vaccine, but in Lombok there were many other possible causes of this disease.

Both this tissue culture vaccine and the LC16m8 strain of Hashizume, which was also produced in primary rabbit kidney cells, met the WHO requirements for safety, potency and stability, and were comparable to calf lymph vaccine in effectiveness for both primary vaccination and revaccination. These 2 strains are the only tissue culture vaccines which have been thoroughly and systematically investigated in the laboratory and also to a limited extent in the field. In the Netherlands, the Lister tissue culture vaccine is kept as the vaccine stock for emergency use, both locally and for supply to other countries; the

LC16m8 vaccine is kept in Japan as a local reserve stock. Either of these vaccines should be suitable for use in the future, should the need arise, when production methods using animal skin are unlikely to be acceptable.

### Silicone Ointment Vaccine

Trials were carried out with freeze-dried vaccine suspended in an ointment, so that it could be squeezed on to the skin in the same way as toothpaste from a tube. An ointment vaccine produced by mixing liquid vaccine lymph with lanoline had been produced at the Lister Institute and in Nigeria in the 1960s, but was no more stable than liquid vaccine. In the early 1970s, the Vaccine and Serum Institute, Berne, Switzerland, developed a similar vaccine, in which freeze-dried vaccinia virus was mixed with silicone ointment. The Smallpox Eradication unit recognized the potential value of such preparations for field use and undertook a development study together with the producer and the WHO reference centres. The titration of this preparation presented a problem, since the vaccine was not readily dispersed. After this difficulty had been solved, the WHO International Reference Centre for Smallpox Vaccine discovered that the heat stability was less than that of the standard freeze-dried vaccine. The manufacturers tried unsuccessfully to improve the stability, and the vaccine was never used in the global smallpox eradication programme.

### EFFICACY OF VACCINATION

The most persuasive evidence that vaccination was effective in preventing smallpox was the progressive decrease in the incidence of the disease that followed its introduction at the beginning of the 19th century, the progressive elimination of the disease from Europe and North America in the middle years of the 20th century and final global eradication of smallpox in 1977. All this happened without the benefit of a controlled trial of the kind that would now be used for evaluating the efficacy of a newly developed vaccine.

Until the Smallpox Eradication unit carried out in 1967-1968 the work described earlier in this chapter, neither the potency of

vaccines nor the methods of inoculation were standardized, so that the difficulty of evaluating vaccine efficacy and the duration of protection was often compounded by the use of vaccine of low potency or by unsatisfactory techniques. Even during the Intensified Smallpox Eradication Programme it was surprisingly difficult to obtain accurate and reliable data on the level of protection against variola major provided by vaccination. The reason for this is that allocation of an individual to the "vaccinated" category has always been made on the basis of the presence of a scar attributed to smallpox vaccination. Prior to the improvements in vaccine achieved after the Intensified Smallpox Eradication Programme was launched, such a scar was sometimes due to bacterial infection rather than the replication of vaccinia virus, especially in the Indian subcontinent, where the rotary lancet was widely used. In addition, studies in Pakistan by Heiner et al. (1971a) showed that many vaccinated persons living in endemic areas experienced subclinical attacks of smallpox, thus augmenting the protection conferred by vaccination.

The best available information, which almost certainly underestimated the protection afforded by vaccination, came from several sets of data on secondary attack rates among vaccinated and unvaccinated family contacts of smallpox cases in Bangladesh, India and Pakistan reviewed in Chapter 4 (see Table 4.12). Cases involving substantial numbers of contacts (100 persons) were selected and the rates of protection afforded by vaccination were calculated (Table 11.25); they varied between 90.7% and 97.1%. In these field studies neither the lapse of time since vaccination nor the potency of the vaccine as administered was known, so that it was impossible to determine the reasons for the occurrence of cases of smallpox among vaccinated contacts. The most likely reasons were the use of unsatisfactory vaccines many years earlier or a long period of time since primary vaccination in areas in which revaccination was uncommon.

When confronted with an outbreak of smallpox, it was usual for public health workers to vaccinate or revaccinate all close contacts of index cases (see Chapter 10). Some of these contacts would not then have been infected with variola virus, but others were probably incubating the disease. The studies just described provide some data on the protection provided by post-exposure vacci-

nation (Table 11.26). Although the numbers are small and not statistically significant in some individual studies, all the analyses showed a lower rate of occurrence of smallpox in previously unvaccinated family contacts who were vaccinated after exposure. The level of protection was greater when previously vaccinated subjects were included (Heiner et al., 1971a). Even when post-exposure vaccination did not prevent the occurrence of smallpox, it often mitigated its severity. Rao (1972), for example, recorded that 8.8% of cases of smallpox occurring in subjects who underwent primary vaccination after exposure were of the modified type, compared with 1.1% among those never vaccinated and 24.7% among persons with scars of primary vaccination, but not vaccinated after exposure.

Mack et al. (1972) succinctly summarize their views on the determinants of infection with smallpox as follows:

"For contacts of any given vaccination status, the rates for protection did not vary with the age, sex or disease severity of the introducer, or with the age or sex of the contacts. Neither did they vary by season, by the closeness of the kinship between contact and introducer (i.e., siblings, cousins, uncle-nephew, etc.), by their housing relationship (i.e., same or different house within the compound), by caste, by occupation of the household head or by the house construction material."

Thus vaccination status was overwhelmingly the most important factor in determining the occurrence of infection.

Even though controlled trials were never carried out with smallpox vaccine, it is apparent that it was very effective in preventing smallpox. Clearly, a potent vaccine was required, so that protection was ensured, although such protection declined with the passage of time. Smallpox vaccination had the great advantage over most other types of immunization that it was very easy to deter-

mine when a successful take had been achieved, especially after primary vaccination, and the resulting scar provided permanent evidence of it. The general medical opinion, on which the International Health

Regulations for smallpox vaccination were based, was that successful vaccination or revaccination within the previous 3 years provided virtually certain protection against smallpox.

### INTRODUCTION

When the Intensified Programme began, in 1967, South America presented the best prospects in the world for the eradication of smallpox. By that time, a single country, Brazil, was reporting almost all cases in the Americas (Table 12.1); and there was little reason to suppose that important areas of endemicity existed elsewhere, although the possibility that unreported foci of smallpox were present in other countries would have to be investigated. Brazil, although a very large and populous country, was small by comparison with the extensive endemic regions of Africa and Asia. Moreover, its relatively advanced health system and its wide-reaching transport and communications network offered promise that an effective programme could be conducted.

In the global strategy of eradication, it was logical to give priority to interrupting transmission in South America. Once that had been achieved, it should be easy to keep the

continent free of smallpox because the risk of a case being imported from as far away as Africa or Asia was small. The resources initially available for the programmes in South America could then be released for use elsewhere.

A regional programme for the eradication of smallpox in the Americas had begun in 1950 pursuant to a resolution of the XIII Pan American Sanitary Conference (Pan American Health Organization, 1971a). This action was strongly supported by the Director of the Pan American Sanitary Bureau (see box), Dr Fred L. Soper, a vigorous proponent of the concept of eradication (Pan American Sanitary Organization, 1949). The decision was reached only 2 years after the commencement of the Bureau's programme to eradicate *Aedes aegypti*, the mosquito vector of yellow fever, from the Americas. Dr Soper considered the latter action to be a "landmark in international health...the first official recognition by an international health organization of regional responsibility for the solution of a

### The Pan American Health Organization and the WHO Regional Office for the Americas

The origin of the Pan American Sanitary Organization (later known as the Pan American Health Organization—PAHO) dates from December 1902, when, at the First General International Sanitary Convention of the American Republics, a series of agreements pertaining to quarantine regulations for the Americas were adopted. To oversee their implementation, to receive reports from governments and to staff periodic meetings, a permanent executive body was created—the International Sanitary Bureau, subsequently renamed the Pan American Sanitary Bureau. Over the next 45 years, the Bureau's activities were largely concerned with this function. Its modest budget was covered by an annual subvention from each of its Member governments.

By virtue of a formal agreement with the World Health Organization, signed in 1949 and approved in the same year by the Second World Health Assembly, the Pan American Sanitary Bureau undertook to serve as the WHO Regional Office for the Americas, but, in deference not only to tradition but also to the continued existence of the Pan American Sanitary Organization, it would retain its own name and identity (Howard-Jones, 1980).

The regular budget of PAHO is financed from two sources: approximately one-third of the total is covered by an allotment from WHO deriving from the contributions of the Organization's Member States throughout the world; the remaining two-thirds are funded by the Member countries of PAHO.

health problem involving an entire continent" (Soper, 1951). The Pan American Health Organization (PAHO) assisted many countries in the development of laboratories to produce freeze-dried smallpox vaccine and many undertook mass vaccination campaigns, some with bilateral assistance.

By 1959, smallpox transmission had been interrupted in all but 5 countries of South America (Table 12.1), of which 3—Brazil, Colombia and Ecuador—were recording large numbers of cases every year. Between 1950 and 1959, the two latter countries had embarked on national programmes to attempt to eliminate the disease. In 1955 Colombia

initiated a systematic mass vaccination campaign, which was completed in 1961. Ecuador began a similar campaign in 1958, which likewise ended in 1961. Bolivia, which recorded 7 cases in 1959, had just completed a 2-year mass vaccination campaign and appeared to be on the verge of interrupting transmission (Frederiksen et al., 1959). Argentina, with comparatively high levels of vaccinal immunity throughout the country as a result of intensive vaccination campaigns, reported only 36 cases in 1959, primarily in provinces adjacent to Brazil.

Between 1959 and 1966, Argentina, Bolivia, Colombia and Ecuador interrupted ende-

<sup>a</sup> Data from the WHO Smallpox Eradication unit based on special reports from governments and reviews of national data. The numbers differ slightly from some official reports published elsewhere (World Health Organization, 1980).

<sup>b</sup> Cases and outbreaks known or believed to have been imported.

### Variola Major and Variola Minor

In most parts of the world in 1967, variola major was the variety of smallpox which was endemic. The much less severe variola minor was present in only 3 areas: South America, southern Africa and the Horn of Africa. Variola major had been endemic in most parts of South America since the 16th century, but in the early 1900s it had begun to be replaced by variola minor. The last known case of variola major occurred in Ecuador in 1962.

The differences in severity between the two forms of smallpox resulted in different responses by health authorities and patients when outbreaks occurred. Variola major was widely feared and its occurrence usually induced health authorities to respond vigorously with vaccination campaigns. In contrast, variola minor often tended to be regarded in the same light as measles or chickenpox. In fact, the disease was called *alastrim* in South America rather than smallpox. Patients with variola minor, instead of being confined to bed by the severity of the toxæmia, as with variola major, often remained mobile and thus were in contact with a greater number of susceptible persons. On the positive side, vaccination, even if performed long before, protected against variola minor more effectively than against variola major. The South American programme must be seen in this setting.

mic transmission. Few cases were detected in other countries, except Brazil and Peru, and most of those could be traced to importations from Brazil. In 1963, Peru, which had last recorded cases in 1954, experienced a serious setback when a major epidemic developed in Loreto Department in the Amazon basin adjacent to Brazil. Before detection, the outbreak had spread widely in the Amazon area and into the Andes and cases had occurred in Lima, the capital. A repeat vaccination campaign interrupted transmission in 1966.

By 1967, Brazil appeared to be the only endemic country in the Americas (Fig. 12.1). Uncertainty existed, however, because Brazil shares a border with all but two countries of South America and most border areas are in remote regions of the Amazon basin, in which there were few health centres to report cases if they did occur. The fact that all known cases were of the mild variola minor type made it less probable that outbreaks and cases, if present, would be detected and reported. However, in these sparsely populated areas, it seemed unlikely that the foci—if indeed they existed—would be extensive.

The eradication of smallpox in South America thus appeared to be a less formidable task than in other endemic regions of the world; primarily, it implied the interruption of transmission in Brazil. Indeed, of the continents in which smallpox had been en-

Fig. 12.1. South America: year of last endemic case of smallpox and number of reported cases occurring between 1967 and 1971 (figures in parentheses). The year shown for each country is that in which the continuing transmission of smallpox is believed to have ceased. Cases recorded in subsequent years are known or thought to have resulted from importations. Transmission in Peru ceased in 1954, but smallpox was reintroduced in 1963 and persisted through 1966.

**Plate 12.1.** Peruvian vaccinators pose under a banner at the conclusion of a training programme in 1968. Both smallpox and BCG (tuberculosis) vaccines were given; hence the banner reading "For a Peru Free of Tuberculosis and Smallpox".

demic in 1967, South America was the first to interrupt transmission. The last known case occurred in the city of Rio de Janeiro on 19 April 1971.

### REGIONAL STRATEGY AND ALLOCATION OF RESOURCES

From the point of view of cost-effectiveness and on epidemiological grounds the programme called for a concentration of available resources and support in Brazil, while providing to neighbouring countries such assistance as was required to develop surveillance and outbreak containment programmes in contiguous areas. If extensive endemic areas were found in neighbouring countries, additional resources could be provided. A more costly but arguably more reasonable approach would have added systematic vaccination campaigns in adjacent high-risk areas to create a partial barrier against the spread of smallpox. However, the strategy evolved along completely different lines.

Simultaneous mass vaccination campaigns throughout South America were proposed. The rationale is summarized in a report of the PAHO Secretariat to the XVII Pan American Sanitary Conference:

"...it is possible to eradicate smallpox in the Americas by immunizing the population at risk, within a relatively short time... although good coordination of all health services can be achieved for the smallpox eradication program or national smallpox vaccination programs, the same cannot be said of maintenance programs. This underlines the need to carry out smallpox vaccination programs simultaneously in as short a time as possible. If this is done and smallpox disappears, and good epidemiological surveillance services are established, then the intervals between revaccination may be gradually increased..." (Pan American Health Organization, 1967).

Conceptually, the strategy of mass vaccination did not differ from eradication programmes of previous decades. Epidemiological surveillance was considered to be important only after smallpox had disappeared. The traditional approach was deeply

<sup>a</sup> From WHO and PAHO financial records and vaccine distribution records.

ingrained and change was stubbornly resisted both by PAHO staff and by national programme directors. In Brazil, the detection of cases and the containment of outbreaks were introduced in some states only in 1969, and not until 1971 were these measures applied on a country-wide basis.

The provision in the plan to continue revaccination campaigns after the disappearance of smallpox may seem paradoxical, but it reflected the prevailing scepticism about the feasibility of eradication. Many health officials at that time believed that smallpox eradication could be achieved only if virtually all persons everywhere were vaccinated and periodically revaccinated. Experience with programmes for the eradication of malaria had shown that it was impossible to reach entire populations; for example, Indian tribes in the Amazon were rarely contacted by civil or health authorities. The concept that eradication could be achieved by stopping transmission of the virus without requiring everyone to be vaccinated was difficult to accept.

Because of the belief in the need for simultaneous mass vaccination throughout the continent, PAHO signed agreements with numerous countries—Argentina, Bolivia, Brazil, Chile, Colombia, Cuba, Paraguay, Peru, Uruguay and Venezuela—late in 1966 and early in 1967 which called for national vaccination campaigns. Some financial support was also provided by PAHO in certain

years to Ecuador, Guatemala, Haiti, Honduras and Mexico. Special programmes were planned in all countries except Chile and Venezuela (in which maintenance vaccination was expected to be performed by the health services), the newly independent Guyana (formerly British Guiana), the French Overseas Department of French Guiana and the then Dutch colony of Suriname. For reasons which are not clear, Guyana was ignored and no special contact was made with either the French or the Dutch government until the end of the programme, when the authorities concerned were requested to co-operate in certifying the absence of smallpox.

WHO and PAHO expenditures (including the value of vaccine distributed) in support of national programmes reflected the strategy (Table 12.2). In 1967, 9 countries received financial support through PAHO; of the total expenditure, only 42% were earmarked for the programme in Brazil.

Mass vaccination campaigns of some form were eventually conducted in 8 countries (see box). The data available for these campaigns are incomplete, consisting primarily of numbers of vaccinations reported to have been performed in different areas. Few campaigns undertook more than perfunctory field assessments to determine the proportion of persons actually vaccinated and the proportion of vaccinations which were successful. Areas in which reasonably extensive mass campaigns were conducted are shown in Fig. 12.2.

A. URIBE

**Plate 12.2.** Peru conducted an extensive vaccination campaign throughout the departments of the Amazon basin where the risk of importations of smallpox from Brazil was greatest. In these areas, the teams relied heavily on boats for transport, like the specially assigned launch shown here.

**Fig. 12.2.** South America: areas in which systematic mass vaccination programmes were completed, 1967–1972.

The total number of vaccinations reported to have been performed in each of the countries, both in mass campaigns and by the established health services, is shown in Table 12.3.

Only Chile, French Guiana, Paraguay and Suriname did not conduct some type of special vaccination campaign, and, with the exception of Paraguay, there was little motivation or need for them to do so. Chile had no border with Brazil and was thus at minimal risk of imported smallpox, while French Guiana and Suriname, with small populations mainly settled along the coast, had scarcely any communication with Brazil.

Paraguay, on the other hand, sharing a border with Brazil and receiving many travellers from that country, was at unusually high risk. Because of fiscal constraints, however, it was unable to carry out a special programme. A mass vaccination campaign had been conducted between 1958 and 1960, during which 86% of the population was said to have been vaccinated. After that time, routine vaccination was offered in health centres. During May and June 1971, a WHO–Paraguay team conducted a search for cases and also performed scar surveys in several

areas to assess the level of immunity (*Wkly epidem. rec.*, 1971a; Table 12.4). No cases of smallpox were found, and 78.5% of those surveyed bore vaccination scars. It was apparent that the existing health services had done reasonably well in sustaining immunity. A costly special campaign might have improved the levels of immunity, at least among young children, but, as was apparent in retrospect, it was not needed.

Information about smallpox in South America from 1967 to 1971, other than in Brazil, is fragmentary. Little was done until 1971 to improve reporting systems, and the investigation of cases was often perfunctory. Uruguay promptly detected and documented 4 importations in 1968 and 1969, and French Guiana similarly dealt with 1 importation in 1968, but these were the exceptions. In Argentina, nothing is known of the 30 reported cases in 1967, which may have been importations, mistaken diagnoses or a combination of both. Argentina's outbreak of 24 cases in 1970 was actually discovered and

investigated by Brazilian teams, who subsequently informed the Argentine health authorities of the occurrence. An episode in Colombia illustrates that even cases diagnosed as smallpox by health staff were sometimes not reported to the national authorities. In 1971, during a special search for possible undetected cases in the Amazon basin, a WHO-Colombia team was informed by a hospital director of 4 cases of smallpox which had been diagnosed in November 1970 in a border town. No report of these cases had been forwarded. The team discovered that the cases concerned were actually misdiagnosed cases of chickenpox, but no one knows how many other outbreaks may have been detected and not reported during earlier years in this and other parts of the Amazon basin. That these isolated regions contained many susceptible individuals was documented by the WHO-Colombia team, which conducted a scar survey in a suspect area. Less than 20% of the children under 5 years of age had ever been vaccinated; among those aged 5-14

### Special Vaccination Campaigns Between 1967 and 1972 in South America, excluding Brazil

*Argentina* (1970 population, 23 962 000): Campaigns were conducted on a province-by-province basis with high levels of vaccination coverage in some provinces and less than 50% in others. The first to be vaccinated were the inhabitants of some provinces in the north, bordering on Brazil, and of provinces in the far south of the country. Subsequent provincial campaigns followed in no logical sequence; no campaign was conducted in the capital or the vast area constituting Buenos Aires Province. In all, some 7.8 million vaccinations were reported to have been performed during the campaign.

*Bolivia* (1970 population, 4 325 000): Bolivia had conducted a mass campaign in 1957-1958 during which 2.4 million persons had been vaccinated, a figure equivalent to about 75% of its population at that time. During a repeat campaign, begun in 1963 and concluded at the end of 1968, 3.7 million people were vaccinated, a figure equivalent to 81% of the population. A third campaign was initiated in 1969, with most of the resources concentrated in 6 of the country's 8 departments (those adjacent to Brazil). The number of people reported to have been vaccinated was equivalent to 82% of the population of the 6 departments concerned.

*Colombia* (1970 population, 20 803 000): Between August 1967 and the end of 1972, campaign staff performed 13.2 million vaccinations in the highland areas. No campaigns were conducted in the Amazon basin adjacent to Brazil, the area at greatest risk.

*Ecuador* (1970 population, 5 958 000): During vaccination campaigns conducted throughout the country, 5 million vaccinations were recorded between 1967 and 1972. A survey conducted in 45 localities in 1972 revealed the presence of vaccination scars in 41% of individuals under 5 years of age, in 85% of those aged 5-14 years, and in 88% of those aged 15-19 years.

*Guyana* (1970 population, 709 000): A mass campaign was conducted in 1970 during which 536 000 persons were reported to have been vaccinated.

*Peru* (1970 population, 13 193 000): A special campaign in Peru was conducted in 1967-1972, primarily in the eastern departments of the country bordering on Brazil and in other departments considered to have the least adequate health services. During the campaign, 5.6 million vaccinations were reported to have been performed.

*Uruguay* (1970 population, 2 808 000): Personnel of the existing health facilities performed most of the vaccinations, recording 1.3 million in all, during the period 1967-1971. An additional 650 000 vaccinations were given in the course of special campaigns. Until 1971 the thermolabile liquid vaccine rather than the freeze-dried product was used and many of the vaccinations were thought to have been unsuccessful.

*Venezuela* (1970 population, 10 962 000): A well-organized and well-evaluated vaccination campaign was conducted throughout most of Bolívar State from August to November 1970 and from April to June 1971. This was a high-risk area bordering on Brazil in which the population was scattered and access to health facilities was limited. Among the 289 000 residents, a vaccination coverage of 91.6% was achieved.

years living in rural areas, only half had previously been vaccinated. From these and other data collected during the period 1971-1973, it was concluded that smallpox had not been sustained in the sparsely populated Amazon border areas. However, neither surveillance nor high levels of vaccinal immunity played a significant role in the attainment of this smallpox-free status.

### THE PROGRAMME IN BRAZIL

During the 1950s Brazil, unlike other countries in the Americas, conducted no nation-wide vaccination campaigns. Local authorities, according to their interest and motivation, vaccinated people in cities and towns when there were outbreaks, but no

**Plate 12.3.** Posters were produced in many countries. This one in Colombia says, "Smallpox vaccine protects the whole family".

programme was carried out in the country as a whole. Between 1950 and 1960, comparatively few cases of smallpox were recorded for a country so populous, the number ranging from a low of 749 in 1950 to a high of 6561 in 1960. However, reports of cases at that time were received from only a few rural health units operated by a special government service and from some hospitals in state and territorial capitals. In fact, only a single city, São Paulo, had a reasonably comprehensive reporting system (Morris et al., 1971). Thus, the actual number of cases was almost certainly many times greater than that recorded.

In 1958, Brazil had joined other PAHO Member States in adopting a resolution of the XV Pan American Health Conference to eliminate smallpox from the Americas. This action was reaffirmed in 1961 by the Charter of Punta del Este, which called on all governments in the Americas to take immediate action "to eradicate malaria and smallpox from the Hemisphere" (Pan American Health Organization, 1973). Shortly afterwards the Oswaldo Cruz Institute in Rio de Janeiro began the manufacture of freeze-dried vaccine.

In 1962, Brazil launched a national campaign against smallpox (Rodrigues, 1975). By the end of 1965, 24 million vaccinations had been performed in a population of 84 million. The initiative for the campaign rested with the authorities of the separate states and territories, few of which were strongly motivated. Not many of the staff were employed at the federal level and only one of them travelled to the field to assist states in developing and monitoring programmes. The campaign was considered to have been satisfactorily executed in no more than 4 of the 27 states and territories. The number of reported smallpox cases throughout the country decreased from 9763 in 1962 to 3623 in 1966. However, because the reporting system had shown little improvement over this period, the decreasing incidence figures meant little.

Interest in the programme heightened in 1965 with the introduction of a new vaccination technique—the jet injector gun. With assistance from PAHO, a special pilot programme was undertaken in the northern Amazonian territory of Amapá by a combined Brazilian–United States Communicable Disease Center team. The team members evalu-

### Smallpox Cases in the Americas, Excluding Brazil, after 1966

Outside Brazil, only 60 cases of smallpox were reported in the Americas after 1966. All were in areas adjacent to Brazil. Except for 30 cases in northern Argentina in 1967, when sources of infection were not identified, all could be traced to importations. Because surveillance was poor throughout the areas neighbouring Brazil, other importations probably occurred but did not result in sustained transmission.

- *Argentina* (1967): Thirty reported cases of which 27 were in Misiones Province, which borders on Brazil, 2 in Formosa Province and 1 in Santa Fé Province, both of which provinces are in the north of Argentina although some 400 kilometres from the nearest endemic Brazilian areas. None of the cases was investigated nor were efforts made to trace the source.

- *French Guiana* (1968): One case, in a Brazilian traveller, in the Amazonian area of the country (*Wkly epidem. rec.*, 1968a).

- *Uruguay* (1968, 1969): Two cases in 1968 and 3 in 1969 resulting from 4 importations from the adjacent, heavily endemic state of Rio Grande do Sul, Brazil. Only 1 secondary case occurred.

- *Argentina* (1970): Twenty-four reported cases between April and June in the border town of Colonia Alicia, Misiones Province. The outbreak was detected by epidemiologists from Rio Grande do Sul State, Brazil. The first case, in a 19-year-old man, was diagnosed in a Brazilian hospital situated 100 kilometres from Colonia Alicia. The patient reported having been exposed to cases in Argentina. Investigations, carried out first by a Brazilian team and subsequently by Argentine authorities, revealed an outbreak of 24 cases which had occurred after importation from a nearby Brazilian border town (*Wkly epidem. rec.*, 1970c). Following containment of the outbreak, Argentina undertook a mass vaccination campaign in Misiones and the neighbouring provinces, during which 443 000 people (84% of the population) were vaccinated (Rodrigues, 1975).

Table 12.5. Brazil: comparison of vaccination campaigns using the multiple pressure technique (Belém) and the jet injector (Macapá)

	Belém <sup>a</sup>	Macapá <sup>b</sup>

<sup>b</sup> Vaccination at established sites and by mobile units, as well as door-to-door.

ated the cost and efficacy of vaccination with jet injectors in relation to vaccination utilizing the conventional multiple pressure technique (Millar et al., 1971) (Table 12.5). With the use of the jet injector an average of 259.5 persons were vaccinated per worker-day, compared with a corresponding figure of 68.4 when the multiple pressure technique was employed. The cost per vaccination was

US\$0.022 with the jet injectors and US\$0.067 using multiple pressure vaccination. Moreover, the jet injectors produced a higher proportion of successful vaccinations. The members of the group responsible for the trial were enthusiastic and recommended a renewed effort to eradicate smallpox. They proposed that a federal director and staff should be appointed to help to organize and

BY COURTESY OF D. A. HENDERSON

**Plate 12.4.** The demonstration in 1965 of the efficacy of the jet injectors provided an important stimulus to Brazil to undertake an effective national smallpox programme. This device could vaccinate as many as 1000 persons each hour.

execute state vaccination campaigns throughout Brazil, and that jet injectors should be provided in order to complete the campaigns, as they stated, "in months instead of years". It was also recommended that state personnel should immediately be selected and trained in the organization of surveillance programmes, a recommendation that was sound in principle but destined to be ignored.

#### DEVELOPMENT OF THE BRAZILIAN NATIONAL PROGRAMME, 1966

The demonstration by the Amapá team of the efficacy of the jet injector and the decision in May 1966 by the Nineteenth World Health Assembly to undertake an intensified global eradication programme persuaded the Brazilian authorities to begin a new national programme.

On 31 August 1966, a federal decree was promulgated which required an intensification and coordination of public and private activities throughout the country to combat smallpox in all its clinical forms with a view to achieving the eventual eradication of the disease. The aim was to conduct a mass

vaccination campaign among the population at large, state by state. It was expected that a surveillance system would be developed to detect and contain outbreaks but surveillance was not intended to begin until each state had completed its vaccination campaign.

Federal financial assistance was given to augment vaccine production at the Oswaldo Cruz Institute (Rio de Janeiro) and plans were formulated for the development of freeze-dried vaccine production at the Institute for Biological Research (Pôrto Alegre) and the Butantan Institute (São Paulo). To aid these laboratories, as well as others in the Americas, PAHO arranged for the Connaught Laboratories of Toronto, Canada, to serve as a reference laboratory to certify vaccine potency and purity and to provide the staff of the assisted laboratories with technical support and training (see Chapter 11).

Provision was made for additional staff for the Brazilian programme. Twelve full-time professional workers—8 medical officers and 4 administrative staff—were assigned to the national eradication programme by the federal Foundation of Special Public Health Services. Foundation personnel, in contrast to most employees of the national health ser-

vice, were paid sufficiently large salaries to permit them to work full time in the campaign. PAHO was asked to recruit 3 medical epidemiologists and a statistician, and to provide 26 vehicles and 72 jet injectors, as well as equipment for the vaccine production centres. Vaccination was to be undertaken state by state, with the great majority of field workers to be locally recruited and trained, and discharged when the programme was completed. Workers were expected to have had 6 years of education and supervisors 12 years. Those performing especially well as supervisors and on the assessment teams were to be retained for service in other states.

The programme was launched in November 1966, and by the end of the year 452 000 persons had been vaccinated. Although it was a hopeful beginning, the subsequent development of the programme was hampered by erratic federal commitment, frequent changes in leadership and serious problems with the quantity and the quality of vaccine produced. The outcome, only a few months before the last case occurred, was anything but certain.

### THE BEGINNING OF THE VACCINATION CAMPAIGN, 1966-1967

The initial plan called for a campaign (Table 12.6) which in 3 years would reach more than 90% of Brazil's population (95.8 million in 1970). The projected targets were highly ambitious and not until the last quarter of 1969—fully 3 years after its commencement—did the programme achieve the expected momentum (Fig. 12.3). In an endeavour to meet these desired targets, virtually all the time and energy of the staff were directed to the vaccination campaign.

The initial smallpox campaigns were conducted in the north-eastern states, in which socio-economic conditions were the least favourable, operational problems were the most difficult and smallpox incidence was deemed to be the highest (Fig. 12.4). Three states (Sergipe, Rio Grande do Norte and Pernambuco), with a total population of more than 7 million, were thought to have been sufficiently well vaccinated (80% reported coverage) during the 1962-1966 campaign not to need a repeat programme. Only a portion of Piauí State was considered to require vaccination. Alagoas (population 1.6 million), crucially situated between Pernambuco and Sergipe, was selected as the state in which to initiate

Table 12.6. Brazil: numbers of vaccinations planned and performed in the mass campaign, 1966-1971 (millions)<sup>a</sup>

Period	Vaccinations planned	Vaccinations performed

1971	0	12.1
Total	91.6	83.7

<sup>a</sup> Does not include routine vaccinations reported by health units.

operations. An experienced staff, consisting of 60 vaccinators, 16 drivers, 12 team leaders, 1 jet injector technician, and 3 supervisors, launched the campaign at the beginning of the rainy season, in November 1966, and concluded it 5 months later. Meanwhile, campaigns had begun in the rest of Piauí (January), Paraíba (February), Ceará (May) and, at the end of the year, in Rio de Janeiro State. In June, smallpox cases were hospitalized in the federal capital, Brasília, and 34 cases occurred in outbreaks in neighbouring areas. Because of this, a campaign was initiated in Brasília (June) and in the neighbouring state of Goiás (September). Although the outbreak was small and the attention it received was perhaps not warranted, the

Fig. 12.3. Brazil: number of vaccinations performed by trimester, 1967-1971.

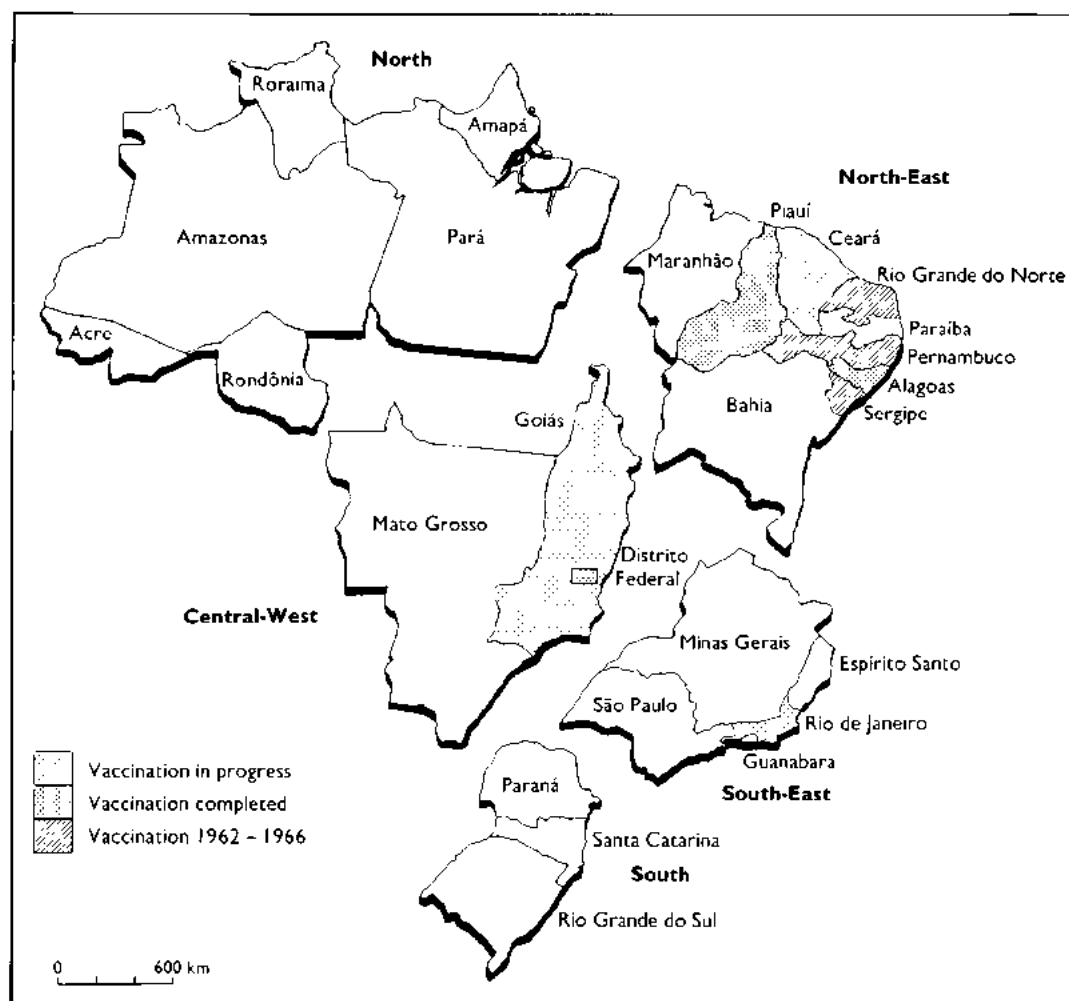

Fig. 12.4. Brazil: status of the smallpox vaccination programme, by region, December 1967.

publicity associated with a campaign in the federal capital was helpful in promoting the programme nationally.

The vaccination campaign within states was undertaken on a *município*-by-*município* basis (as an administrative unit a *município* corresponds roughly to a county in the USA). There were then some 4000 *municípios* in Brazil. An intensive vaccination campaign of several days' duration was conducted in each *município* before the team or teams moved to the next. The inhabitants of the state capitals were usually the first to be vaccinated, after which the teams moved to more sparsely populated areas. Each team consisted of 4 or 5 vaccinators, a leader and a driver. Groups of 4 teams were directed by an area supervisor. Jet injectors were used for vaccination at collecting points in both urban and rural areas.

When bifurcated needles became available in 1968, they were used primarily in rural areas. All individuals aged 3 months and over were vaccinated.

### The Outbreak in Branquinhas

Although progress in terms of numbers vaccinated was far less in 1967 than had been expected, a more serious problem came to light in July of that year. Twenty-one cases of smallpox were reported from the town of Branquinhas, Alagoas State, which had completed its systematic vaccination campaign only 3 months before. The *município* of Branquinhas had a population of 6317, of whom 1435 lived in the town. A vaccination team had spent 6 days in the *município* and reported that it had performed 6558 vaccinations, a

**Plate 12.5.** Leo Morris (b. 1935), a statistician, worked with Henderson at the Communicable Disease Center during 1966 for the programme in western and central Africa. He joined the programme in Brazil in 1967 as a WHO staff member and was instrumental in developing the national weekly surveillance report and in promoting the investigation of outbreaks, including the one at Branquinhas, which demonstrated the need for continuing assessment of the vaccination campaign.

number larger than the estimated population. There seemed to be only two likely explanations: either many vaccinations had been unsuccessful because of substandard vaccine or poor technique, or the number of reported vaccinations was exaggerated.

Staff attached to the national campaign investigated immediately and found not 21 but 51 cases of smallpox. Only 2 cases had previously been vaccinated (Morris et al., 1970b). A survey of randomly selected households in the city revealed that vaccination take rates were satisfactory but that only 49% of the inhabitants had actually been vaccinated by the teams. Surveys in two rural areas showed that 75% of the residents had been vaccinated in one of them and nobody in the

other. It was apparent that records had been falsified and that supervision and planning were poor.

### The Repercussions of the Branquinhas Outbreak

Until the Branquinhas outbreak, the national programme director had refused to assign even a few personnel and vehicles to "do nothing but evaluate", as he expressed it. As in many other programmes, it was believed that all possible resources should be deployed in administering vaccine. Branquinhas was a turning-point. It was agreed that assessment teams must be created, and these began work early in 1968 (*Wkly epidem. rec.*, 1968c). Each comprised 4 persons, who visited vaccinated areas about 7-9 days after the completion of a programme. A household probability survey was conducted, in which, in a sample of households, the vaccination coverage of all household members was determined, as were the take rates for primary vaccination among children between 3 months and 5 years of age (Lavigne de Lemos & Morris, 1969). With improved supervision and a knowledge that their work was being continually assessed, the teams consistently achieved much better vaccination coverage. The data from 26 *municípios* in 2 states—Minas Gerais and São Paulo—compiled in 1969 illustrate this (Table 12.7).

In most *municípios*, independent assessment showed that more than 90% of individuals aged between 3 months and 14 years—the age group in which three-quarters of all cases occurred—had been vaccinated. The proportion of older persons vaccinated during the campaign tended to be lower, but a great many of them had already had smallpox or had been vaccinated at some time in their lives. In areas in which less than 80% of those under 5 years of age were found to have been vaccinated, a repeat vaccination campaign was

<sup>a</sup> From *Wkly epidem. rec.* (1969d).

BY COURTESY OF DA. HENDERSON, 1968

**Plate 12.6.** Oswaldo José da Silva (b. 1907), in the centre, was director of the national programme in Brazil, 1967–1968. A former malariologist and PAHO staff member, he was a skilful administrator and was responsible for the establishment of Brazil's national vaccination campaign structure. With him are K.S. Ramakrishnan from the WHO Regional Office in New Delhi and John Copland, administrative officer of the Smallpox Eradication unit in Geneva from 1967 to 1977.

conducted. Primary take rates were usually above 90%, although when revaccination responses were checked, the take rates were usually only 50–60%. Considering the low potency and lack of stability of the vaccine used (see below), the results were surprisingly good.

Because the programme was making less progress than had been planned, and because of the Branquinhas incident, a new director, Dr Oswaldo da Silva, was appointed in September 1967. Dr da Silva had worked in both Brazil and PAHO in the malaria eradication programme and was widely respected for his skills in management and his grasp of logistics. Following his appointment, a more effective organizational structure began to take shape.

Critical to the ultimate success of the programme was the establishment in May 1967 of a national smallpox reporting system and the publication each week of a surveillance report (*Boletim semanal da Campanha de Erradicação da Varíola*), which documented the numbers of cases reported each week, described developments in the programme and recorded the results of investigations by field staff (WHO/SE/73.52, Lavigne de

Lemos & Souza). Fostered by an imaginative young WHO epidemiologist-statistician, Mr Leo Morris, it was modelled on reports of surveillance programmes at the United States Communicable Disease Center, in which he had previously worked. This simple mimeographed report was sent to more than 2000 senior health and programme staff. It served to instruct, to motivate and to give the widely scattered staff a sense of common purpose.

With repeated reminders to states to report cases each week on standardized reporting forms, the notification system gradually improved, but it was apparent from the several field investigations conducted that few of the many cases were being detected. Some of these investigations revealed significant problems. One was an outbreak in a 250-bed children's hospital in Vitória, Espírito Santo State, which was reported in October 1967. Investigation revealed that 51 cases had occurred over a 10-month period. During this time, there had been at least 11 and perhaps 14 separate introductions of smallpox into the hospital; between 36 and 40 children were infected there subsequent to admission for other causes. None of the children had ever been vaccinated; 5 died (Morris et al., 1970a). That hospitals served as important foci for disease transmission was subsequently to be documented repeatedly in Brazil and elsewhere. The proper isolation of patients and the vaccination of staff and of patients on admission to hospital were seldom effectively practised.

By the end of 1967, work had been completed in the Federal District, Piauí and Alagoas. More support was obviously required, and the Ministry of Health requested WHO to provide 178 vehicles (in addition to the 26 which had been supplied in 1965) and 97 jet injectors (in addition to the 122 then in use). Of great help in Brazil was the minimum time-lag between the decision to provide vehicles and their availability. Locally manufactured vehicles could be delivered within weeks of placing an order, whereas in other parts of the world 12–24 months might elapse between order and delivery. The requested supplies arrived early in 1968.

### THE VACCINATION CAMPAIGN GAINS MOMENTUM, 1968

Under Dr da Silva's leadership, the monthly numbers of vaccinations steadily increased

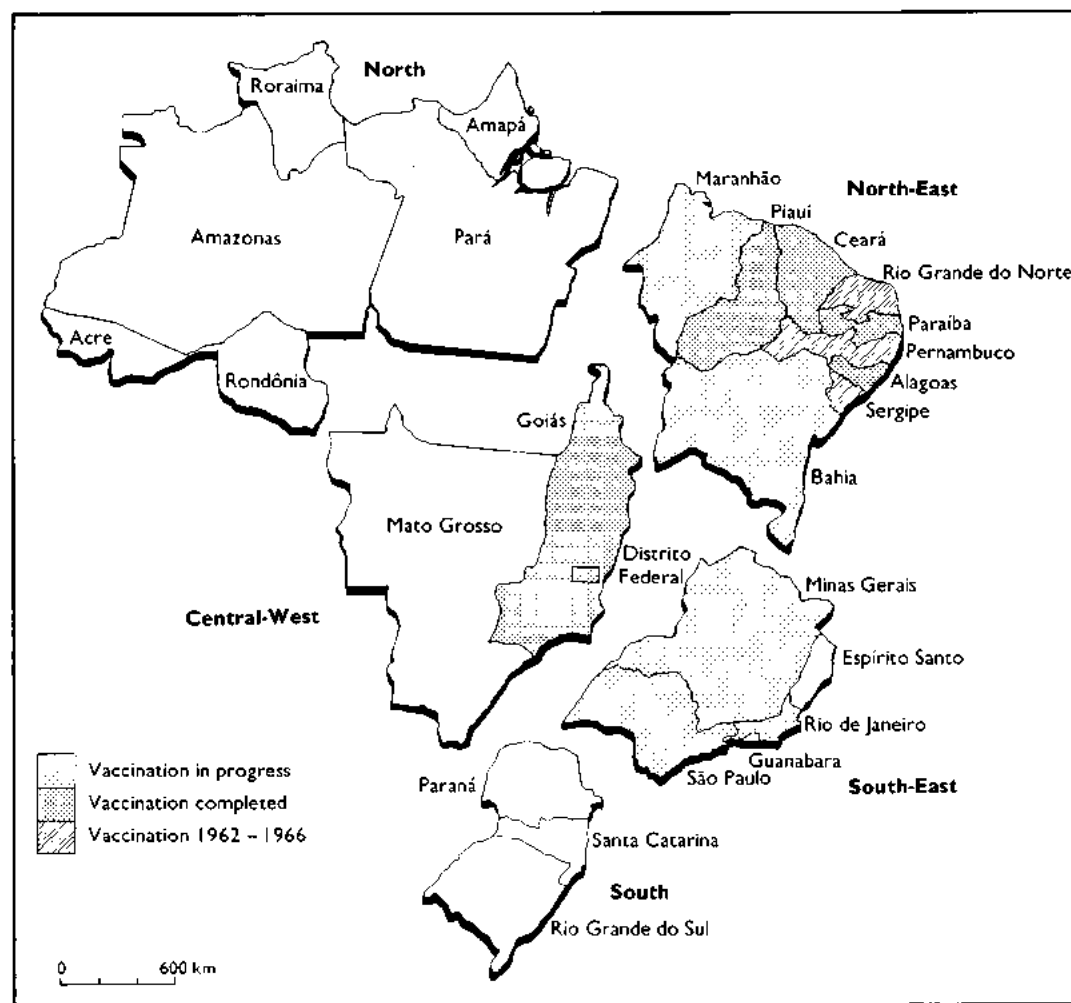

Fig. 12.5. Brazil: status of the smallpox vaccination programme, by region, December 1968.

during 1968; and with a programme of assessment in operation, there was a greater degree of confidence that the numbers reported were accurate. In addition, in states in which the systematic vaccination campaign had been completed, the staff began to investigate some of the cases reported. Virtually nothing was done, however, to strengthen surveillance in the states in which vaccination campaigns had not been conducted.

More than 12 million vaccinations were given in 1968—almost twice as many as in 1967 (Table 12.8). Fully 1000 staff were active in the field. Work was completed in 3 of the 4 states in which vaccination campaigns had been initiated in 1967, and programmes were begun in 3 additional states (Fig. 12.5) (*Wkly epidem. rec.*, 1968b).

The number of reported cases of smallpox showed little change (4372 in 1968 compared with 4514 in 1967), but because reporting was thought to be more complete the staff were encouraged (Table 12.9).

However, at the end of 1968, the government, as a general economy measure, made substantial cuts in the budget for the programme: per diem payments for Brazilian national staff were eliminated, thus curtailing travel; supplementary payments which had permitted senior staff to work full time in the programme were stopped; and the complement of programme staff was reduced to 759. Nearly 9 months elapsed before full support for the programme was resumed. Dr da Silva's target of 5 million vaccinations per quarter or 500 000 vaccinations per week was not to be achieved for another year.

<sup>a</sup> The last case occurred in April.

## THE BEGINNING OF AN EFFECTIVE SURVEILLANCE PROGRAMME, 1969

The concept of assigning at least one epidemiologist to every state, to be responsible for the development of a system which would ensure the prompt transmission of weekly reports of cases from reporting centres and to investigate and contain outbreaks, had been increasingly stressed by the WHO Smallpox Eradication unit. However, neither the Brazilian nor the PAHO staff showed interest. Meanwhile, the efficacy of surveillance-containment activities had become increasingly apparent in eradication programmes, particularly in western Africa. With the aim of stimulating interest in the development of a surveillance programme, a special meeting of all of WHO's smallpox advisers in the Region had been convened in

Rio de Janeiro in April 1968, in which Brazilian national staff also participated. It proved to have little impact.

Finally, in October 1968, Dr Nelson Morais, newly appointed as General Secretary of the Ministry of Health and himself an epidemiologist, was contacted by WHO and persuaded that a special effort should be made to develop a surveillance programme for smallpox which might eventually extend to other infectious diseases. At his urging, a special training programme in the surveillance and epidemiology of smallpox was conducted in São Paulo during January 1969 (*Wkly epidem. rec.*, 1969d). Instruction was provided by staff from the smallpox eradication programme, the Adolfo Lutz Institute and Mr Morris. Those who attended included 15 of the medical officers attached to the smallpox eradication programme who had

I. VERNES, 1970

**Plate 12.7.** Clovis H. Tigre (b. 1938), director of the programme in Rio Grande do Sul State, developed one of the 4 special state surveillance programmes in Brazil which demonstrated the need for national surveillance. The Rio Grande do Sul programme was exceptionally effective and eventually incorporated the administration of many other vaccines, a forerunner of WHO's later initiative, the Expanded Programme on Immunization.

responsibility for the vaccination campaign, plus 3 epidemiologists, Dr Ciro de Quadros, Dr Nilton Arnt and Dr Eduardo Costa, who had recently graduated from the School of Public Health in Rio de Janeiro. The medical officers were to conduct surveillance after mass vaccination had been completed but the 3 epidemiologists were each to be assigned to the populous states of Paraná, Bahia and Minas Gerais, in which vaccination campaigns had not yet been conducted. There they were to undertake surveillance programmes which might serve as prototypes for other initiatives in infectious disease surveillance. The special surveillance programmes in the 3 states began in March and were extended to a fourth state, Rio Grande do Sul, later in 1969 (Suzart de Carvalho Filho et al., 1970). Approximately 35% of Brazil's population lived in these 4 states.

Although Dr Morais was convinced that surveillance was important, the highest priority for Dr da Silva and the senior small-pox eradication programme staff remained the vaccination campaign, then foundering because of the government's curtailment of

funds. There was a reluctance to divert resources to surveillance activities. Only one of the epidemiologists was eventually given a programme vehicle, and then after weeks of discussion. The others were obliged to rely on state health department vehicles, which were rarely available. The only other resources available to them were a driver and a vaccinator, plus whatever help they could recruit from health centres or hospitals. The 3 epidemiologists worked for less than a year before being obliged to resign because of yet another change in the administration of the programme. Subsequently, Dr Arnt and Dr de Quadros were recruited for service with WHO in Africa and Asia, in which they played vital roles in the development of surveillance programmes.

Although the surveillance containment programme that had been set in motion was modest and short-lived, the results proved to be decisive. Through the activities of reporting centres, which would report cases weekly, and through field investigations the epidemiologists soon began to discover large numbers of unreported cases (Azeredo Costa et al.,

No vaccination scar and no history of smallpox	1 021	347	674	466	69.1

1971; Arnt & Morris, 1972, Quadros et al., 1972). In an early report, Dr de Quadros and his colleagues documented their findings in the investigation of 27 officially notified cases. By tracing the sources of the outbreaks and through extensive search to identify all cases in each outbreak, they discovered 33 outbreaks in which 1492 cases had occurred. By extrapolation, the studies suggested that the actual number of cases was 50 times greater than the number being reported. In the studies, residents in all the affected households were interviewed to determine if any had previously contracted smallpox and all were examined for vaccination scars (Table 12.10). A uniform reporting form was designed. Although the population under study consisted only of persons residing in houses in which a case had occurred and so were not representative of the community at large, the proportion of residents in affected households who had ever been vaccinated was 20% or less. This level of vaccinal immunity was far lower than in any other country of South America.

Epidemiological observations documented the fact that smallpox spread widely among household contacts. Of 674 persons who had neither a history of smallpox nor a vaccination scar, 466 (69%) contracted smallpox (Table 12.11). As expected, a previous attack of smallpox provided total protection, but previous vaccination, even if it had been performed many years earlier, was far more efficacious than had been thought. Only 7 of 204 persons with a vaccination scar developed the disease, and among them it was much milder than among the unvaccinated. The vaccine-efficacy ratio showed levels of protection of 90% irrespective of the interval since previous vaccination (Suzart de Carvalho Filho et al., 1970). These findings served to emphasize the need to give priority to primary vaccination over revaccination.

The outcome of the surveillance programme in Paraná State, conducted by Dr de Quadros, was most dramatic. He began the programme in March, 3 months before the mass vaccination campaign commenced in the state capital. Operating alone in a state

discovered and contained the last known outbreak. In all, 30 000 persons were vaccinated during containment operations. The mass campaign gradually moved across the state but the staff found no other outbreaks.

Dr da Silva was increasingly impressed by and supportive of the surveillance programme, but at the same time frustrated by a lack of funds and support for the vaccination campaign. Significant progress was being made only in São Paulo State, which financed the programme with state funds. Exasperated, he resigned in July, and for political reasons Dr Moraes was replaced in September. Three months later the appointment of the 3 epidemiologists was terminated. Dr da Silva was but the second of 5 persons who were to direct the programme between 1967 and 1972, during which period there were 3 different ministers of health.

Such stability as the programme enjoyed was largely provided by the WHO epidemiologist-statistician, Mr Morris, who, with his Brazilian counterpart, continued to produce the weekly *Boletim* and faithfully recorded the substantial increase in the number of reported cases during 1969. Because of the field investigations, the number of cases in the 4 states tripled between 1968 and 1969, from 1681 to 5370 (Table 12.12). Although this was partially offset by a decline in the number of

Table 12.12. Brazil: number of reported cases of smallpox in 4 states in which special surveillance-containment programmes were conducted, 1968-1969

Paraná	218	992
Rio Grande do Sul	459	836
Total	1 681	5 370
Remainder of Brazil	2 691	2 037
Total for Brazil	4 372	7 407

reported cases elsewhere in Brazil, the net outcome was the highest total number of cases to be recorded in the country since 1962. Because of the *Boletim's* extensive circulation, this dramatic increase in the number of cases (Fig. 12.6) attracted wide attention, including that of the press, the Minister of Health and even the President. Although programme staff repeatedly pointed out that better reporting was the probable cause, there was alarm, and support and resources became much easier to obtain.

With additional resources from the government and additional vehicles and jet injectors from WHO, the tempo of the

Fig. 12.6. Brazil: reported cases of smallpox and cumulative numbers of vaccinations, by 4-week intervals, 1967-1971.

vaccination campaign rapidly increased (Fig. 12.7). During the last quarter of 1969, 7.3 million persons were vaccinated compared with only 4.2 million during the third quarter. However, with the departure of Dr Moraes, Dr da Silva and the 3 epidemiologists, surveillance deteriorated. As was revealed in a survey by a WHO consultant, Dr Paul Wehrle, by February 1970, only 16 of the 27 states and territories had surveillance officers responsible for the investigation and containment of cases. At that time, reports on the situation with regard to smallpox during the month of January were available for only 14 of the 27 states and territories. Even in the states to which officers had been assigned, few notification units were submitting weekly reports. Bahia State, for example, had 200 reporting units, most of which reported monthly rather

than weekly. In that state, the consultant found one outbreak that had been reported in November but was not investigated until January. In Pernambuco, only 13 of the 54 reporting posts were found to be currently sending reports. In the other states the situation was not notably better.

### CONCLUSION OF THE VACCINATION CAMPAIGN, 1970

The momentum achieved in the vaccination campaign during the last 3 months of 1969 continued into 1970. Programmes were begun in all of the remaining states, the government allocated additional funds, the USA agreed to provide bilateral assistance, and by the end of the year more than 30 million vaccinations had been performed.

Fig. 12.7. Brazil: status of the smallpox vaccination programme, by region, December 1969.

### The Largest Recorded Outbreak during the Brazilian Programme

The largest recorded outbreak in Brazil occurred in the *município* of Utinga, Bahia State, in 1969. A total of 507 cases occurred in a population of 9277 (Azeredo Costa et al., 1971; Azeredo Costa & Morris, 1975). The outbreak was discovered in August, when a newly created surveillance unit in Bahia investigated a single reported case in the *município* of Bom Jesus da Lapa, 300 kilometres south-west of Utinga. The patient, a resident of Utinga, was already ill when she arrived in Bom Jesus da Lapa. The team immediately went to Utinga and discovered an epidemic which had been in progress since February. No cases had been notified by the local authorities. A house-to-house search in the city revealed 246 cases in a population of 2200. Cases occurred also in the surrounding rural areas, in one of which 154 of the 505 residents (30.5%) had contracted smallpox.

*Results of a Survey in 104 Households with Smallpox in Utinga City*  
(Azeredo Costa & Morris, 1975)

Age group (years)	Number of residents	Number with history of smallpox	Number with vaccination scar	Number fully susceptible to smallpox	Number of cases
≤ 4	103	0	9	94	57
5-14	214	21	32	161	124
15-29	148	55	26	67	50
≥ 30	153	75	46	32	15
Total	618	151 (24.4%)	113 (18.3%)	354 (57.3%)	246

A survey of residents of the 104 infected households revealed that about 25% had a history of smallpox; another 18% had a vaccination scar. Of the susceptible individuals, 69% contracted smallpox. No cases occurred among those who had already had smallpox; 4 cases occurred among those with vaccination scars, the years of vaccination being 1938, 1947, 1965 and 1967 respectively. The last 2 were very mild cases with few lesions. The age-adjusted vaccine-efficacy ratio was calculated to be 94%.

Ironically, the last of the states to begin a campaign was the state of Guanabara (Fig. 12.8) which, in effect, consisted of the metropolitan area of the city of Rio de Janeiro, the headquarters of the national smallpox eradication programme. The health officer in that state had been one of the least cooperative in reporting cases and had vigorously resisted joining in the vaccination campaign, in part because he considered that the attendant publicity would adversely affect the important tourist industry. Not until October 1970 did he finally agree to permit a selective programme of vaccination at schools, factories and construction sites and among the inhabitants of the slums (*favelas*) and rural areas around the city. A hectic campaign commenced in an effort to reach all of the 1500 schools before the end of the school year in December.

The last cases of smallpox to be discovered in Brazil did not occur in the remote areas of

the Amazon basin or in the economically depressed regions of the north-east but in the city of Rio de Janeiro itself, less than 10 kilometres from the national headquarters of the smallpox eradication programme.

### The Last Known Cases of Smallpox in Brazil

In November 1970, it was thought that the last cases of smallpox had been detected in Brazil. For more than 12 weeks, no cases were discovered. However, on 1 March 1971, during the last week of the special house-to-house search and vaccination campaign in high-risk areas of the city of Rio de Janeiro, a vaccination team discovered 2 patients with rash and sent them to the isolation hospital. Investigation quickly revealed that 14 cases in all had occurred in 2 groups of adjoining households. The first patient, who had be-

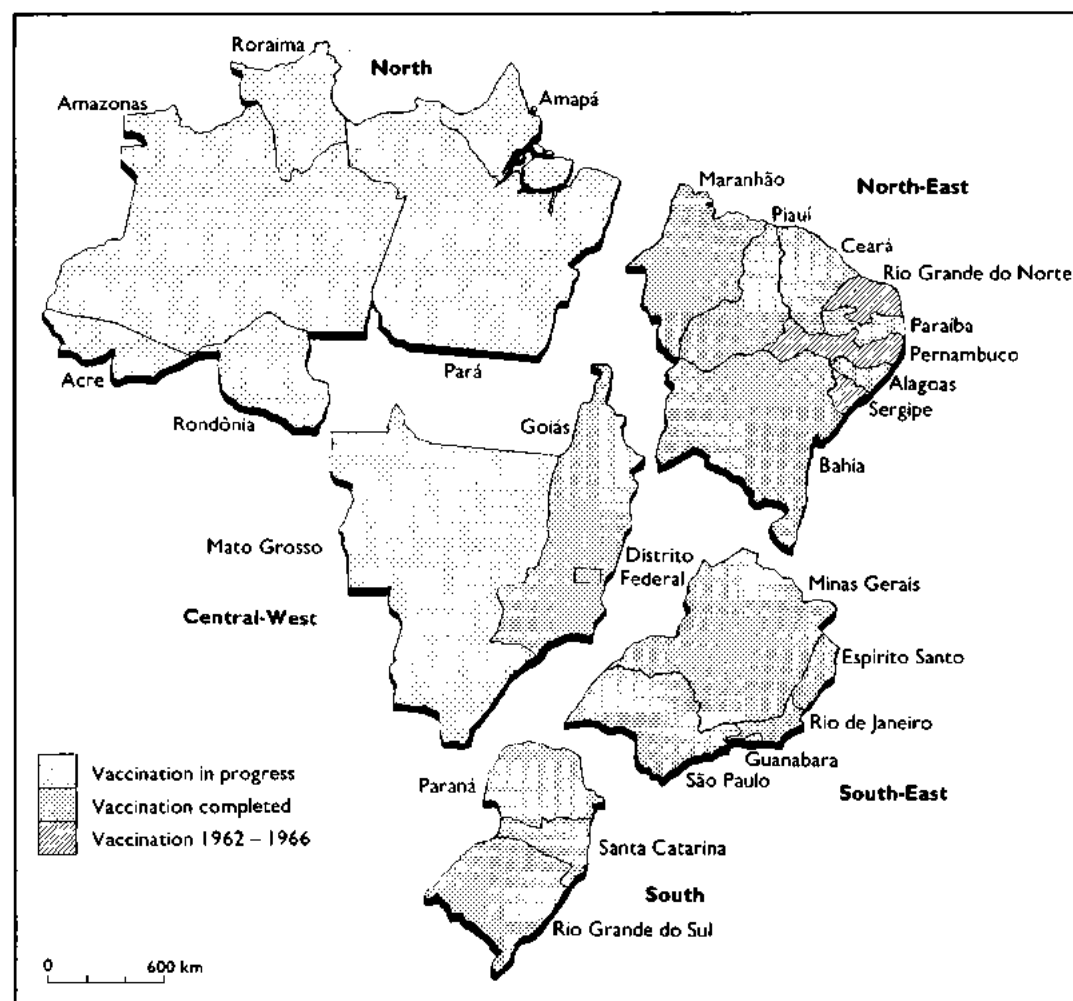

Fig. 12.8. Brazil: status of the smallpox vaccination programme, by region, December 1970

come ill on 22 December 1970, had been displaced from a previously infected area of the city in which many houses had been demolished. Between December 1970 and March 1971, the summer period of seasonally low incidence, smallpox spread slowly.

Intensive search and containment measures were conducted throughout the community. Two additional cases occurred in this area, both of whom were in the incubation period when vaccinated. They were not the last cases, however. The Rio de Janeiro isolation hospital served no better as an isolation facility than did such institutions in most other parts of the world. Three more cases occurred among already hospitalized patients. The third, detected on 19 April, was the last case in the Americas.

#### Expansion of the Reporting Network, 1970-1971

Although the rudimentary surveillance system had been temporarily strengthened by the addition of the 4 epidemiological units in 1969, few suspected cases were investigated or outbreaks contained until late in 1970. The inadequacy of the system until 1971 is apparent from the data presented in Table 12.13.

During 1970, epidemiological surveillance units began to be established throughout Brazil. Each was under the direction of a physician-epidemiologist who had been specially trained by national programme staff. The units were charged with the following responsibilities:

- (1) To establish a network of reporting

Table 12.13. Brazil: number of reported and suspected cases of smallpox and proportion investigated by programme staff, 1967-1973

Year	Number of reported cases	Number of suspected cases	Total	Number Investigated by programme staff	% of reports investigated
1967	4 514	0	4 514	230	5

1972	0	718	718	718	100
1973	0	131	131	131	100

<sup>a</sup> Excludes the states of Paraná, Minas Gerais, Bahia and Rio Grande do Sul, in which special programmes of investigation were conducted (see text).

centres which would report weekly, on a standard form, the presence or absence of suspected cases of smallpox. Each health post would serve as a reporting centre, and in the absence of such a post in a *município*, a responsible official would be asked to provide the requisite information.

(2) To establish and maintain contact with hospitals, physicians, schools, community leaders and any other persons who might be aware of the existence of possible smallpox cases.

(3) To investigate immediately all suspected cases and to undertake the necessary epidemiological and laboratory investigations.

By the end of 1970, surveillance units had been established in 18 states and territories; 2665 reporting centres were in operation.

Meanwhile, smallpox staff joined malaria teams to conduct a systematic programme of search and vaccination throughout the extensive Amazon basin. Five months of work were required, from September 1970 to January 1971; however, no cases of smallpox were detected. Independently, a team of physicians from the International Committee of the Red Cross contacted 20 of 36 Indian tribes in the Amazon basin and reported that they, too, had found no cases among the 4500 individuals whom they examined (*Wkly epidem. rec.*, 1971a).

From 1971 to 1973, Brazil's first national system for disease reporting gradually matured (Table 12.14) under the direction of the last and one of the most able of Brazil's programme directors, Dr Claudio do Amaral, who was later to serve with the WHO smallpox eradication programme in Ethiopia. The number of reporting centres grew from 3243 in 1971 to 6381 in 1973; 444 suspected cases were investigated during 1971 and 718

cases during 1972. Laboratory specimens to confirm diagnosis were obtained from nearly three-quarters of all cases and examined in laboratories in Brazil and the USA (Noble et al., 1970; Schatzmayr & Mesquita, 1970). The systematic vaccination campaign concluded in 1971 with the programme in the Amazon basin and with the revaccination of the population of several states (Pernambuco, Rio Grande do Norte, Alagoas and Piauí) which had been vaccinated during the period 1962-1966 but not subsequently.

In 1972, a national assessment was undertaken during which 778 719 persons in 451 different localities were examined to determine what proportion of their populations bore vaccination scars (WHO/SE/73.51, Amaral et al.). The results are shown in Table 12.15.

The total of 80% with vaccination scars was impressive considering that programmes in some states had concluded as long as 4 years earlier. When the results were examined by state, at least 70% of the population were found to have vaccination scars in all states except Bahia and Ceará, in which the proportions were 59% and 56% respectively.

## NUMBERS OF REPORTED CASES AND DEATHS, 1968-1969

Because of the work of the surveillance officers, data are available for 1968-1969 regarding the age and sex distribution of cases, and the case-fatality rates at different ages (Suzart de Carvalho Filho et al., 1970) (Table 12.16).

Nearly three-quarters of all cases (72.6%) occurred among persons under 15 years of age. Among the 9854 cases, only 75 died—a case-fatality rate of just 0.8%, characteristic of

L. MORRIS

**Plate 12.10.** In 1970, state surveillance units were established throughout Brazil to improve the reporting and investigation of suspected cases. The provision of uniforms, an important fringe benefit, also served to enhance morale.

variola minor. However, among infants under 3 months of age, the case-fatality rate was 16.7% and among those aged between 3 months and 1 year it was 2.0%—more than twice that observed in most other age groups.

### RESOURCES EMPLOYED

Data on national expenditures for the campaign are available only for the period 1966–1971. In all, the government of Brazil spent the equivalent of US\$4 506 369 from its own budget. The World Health Organization and the Pan American Health Organization expended US\$1 763 780 during the same period, primarily for advisers, vehicles, jet injectors, and vaccine and vaccine production equipment, and the sum of US\$892 195 was made available by the United States government. Expenditures by state governments are not included in these figures; in São Paulo they were considerable. Additional costs—far lower than these—were incurred during the subsequent 2 years during which the pro-

programme conducted a variety of search activities to ensure that eradication had been achieved. The national and international expenditures from 1966 to the end of 1971, when transmission was interrupted, thus amounted to US\$7 162 344 overall or about US\$0.077 per head of population (Table 12.17).

Information regarding the number and category of national personnel employed in the programme as well as the numbers of vehicles and jet injectors was compiled at the end of December each year from 1968 to 1971 (Table 12.18).

## SMALLPOX VACCINE PRODUCTION

The development and expansion of facilities for the production of smallpox vaccine in Brazil proved to be a most difficult and frustrating problem. Indeed, the Brazilian programme was unique in that it was possible to interrupt transmission despite the use of vaccines which rarely met accepted standards of potency and stability, and which often contained pathogenic bacteria. The success of the programme testified to a generally well-managed systematic vaccination campaign and vaccine standards that tolerated a substantial margin of error.

In 1967, it had been apparent that large

supplies of freeze-dried vaccine would be required for the systematic vaccination campaign in Brazil, as well as additional quantities for Argentina, Bolivia, Colombia, Ecuador, Paraguay, Peru and Venezuela, in each of which an extensive vaccination campaign was planned. When the programme began, freeze-dried vaccine was being produced in a number of South American countries (Table 12.19).

In 1966, little of the vaccine produced by most laboratories met accepted standards of potency and stability, and most of the laboratories were drying the vaccine in containers of 100 or more doses. Since freeze-dried vaccine, after reconstitution, was as thermolabile as liquid vaccine, it should have been used only on the day it was reconstituted. The result was that either significant quantities were wasted or, if the vaccine was kept for several days after being reconstituted, it suffered a considerable loss of potency.

The Connaught Laboratories agreed to test batches of vaccine regularly and to assist laboratories through consultant visits and training, locally and in Canada. Equipment and assistance were eventually provided by PAHO to laboratories in Argentina, Brazil, Chile, Colombia, Cuba, Ecuador, Mexico, Peru, Uruguay and Venezuela. Support was given to countries that requested it, thus accounting for the allocation of resources

<sup>a</sup>From Rodrigues (1975).

even to countries at little risk such as Chile, Cuba and Mexico. It would have been more logical to concentrate efforts in Brazil, whose laboratories were experiencing the greatest problems. The Connaught consultants, however, were directed to travel throughout the continent assisting laboratories in numerous countries. Less than one-third of their time was spent at the principal vaccine production centre in Brazil, the Oswaldo Cruz Institute, which experienced constant difficulties and never did succeed in producing a consistently satisfactory product.

Data regarding the quality of vaccines produced by the different laboratories in the Americas are regrettably scanty. Each laboratory was supposed to test its own vaccine and to send samples of each batch to the Connaught Laboratories until it was certain that a satisfactory vaccine was being produced consistently; thereafter, 2 batches were to be sent for testing every 3 months. Comparatively few samples, however, were submitted for independent testing. From an assessment of the limited data available from the Connaught Laboratories and from reports of visits by consultants, it would appear that the vaccine produced in Argentina, Chile and Colombia consistently met WHO standards, while that produced in Ecuador and Peru sometimes failed to meet standards of stability—i.e., when the vaccine was incubated at 37 °C for 1 month, its titre fell below an accepted minimum standard. The Brazilian laboratories seldom produced batches of vaccine which met international standards (see Chapter 11). Many batches were low in initial potency and most failed to meet stability standards. Vaccine for use in Brazil's systematic vaccination programme was produced exclusively at the Oswaldo Cruz Institute. Vaccine from the other laboratories was distributed to health centres and hospitals for what was termed "maintenance vaccination."

At the Oswaldo Cruz Institute, much of the vaccinia virus was grown in embryonated hens' eggs. Experience elsewhere had shown that, for technical reasons which are still unexplained, virus harvested from this source rarely met accepted standards of stability. In the endemic countries, none of the laboratories except the Oswaldo Cruz Institute and Brazil's vaccine production centre in Porto Alegre used this method of production. In addition to being unstable, many of the batches from the Oswaldo Cruz Institute failed to meet minimum standards of potency. However, the vaccine which the Institute produced on calves (about half of its production) was little better, in terms either of potency or of stability, and most batches were found to be contaminated with numbers of pathogenic bacteria (coagulase-positive staphylococci and non-haemolytic streptococci). Of 43 batches of Oswaldo Cruz vaccine tested by the Connaught Laboratories as late as 1970, 35 failed to meet accepted stability standards, and 13 of the 43 batches were below minimum standards of potency. In January 1970, 15 vials of Brazilian vaccine were collected from the field and tested; only 2 met the accepted standards of potency. Moreover, as a WHO consultant noted at that time, the vaccine was not labelled as to origin or lot number and no expiry date was stamped on the containers.

Vaccine production units at Recife and Porto Alegre had equally poor records, and although WHO consultants recommended that they should be closed, they continued to produce vaccine. Not until late in 1970, near the end of the programme, did fully satisfactory vaccine become available. At that time, the Butantan Institute in São Paulo began producing a consistently satisfactory vaccine from virus harvested from calves.

Despite the poor vaccine, assessment teams usually found that take rates for primary

Table 12.20. Brazil: number of doses of vaccine produced and number of vaccinations performed, 1967-1972 (millions)

	1967	1968	1969	1970	1971	1972

Total	18.0	21.4	25.9	37.3	18.0	13.9

vaccinations were above 90%. However, to achieve a high proportion of successful takes, it was necessary to ensure that the vaccine was kept refrigerated until the time of use. When refrigeration was available, the take rates were generally satisfactory, but in more remote areas that lacked such facilities, they were not. The results of assessment in Espírito Santo State illustrate this: take rates of 98% were obtained among those vaccinated in urban areas, but in the more remote areas in which refrigeration was a problem, the rates were 88-93%. In other parts of the world, where fully potent and stable vaccine was available, take rates of 98% or higher were the rule, even when vaccine was kept at ambient temperatures for a month or longer.

The large quantities of vaccine reported to have been produced in Brazil (Table 12.20) far exceeded the amounts required for the numbers of vaccinations performed. Yet, despite the large volume of production reported, available vaccine supplies so frequently dropped to critical levels in Brazil that reserve supplies were requested from and donated by Argentina in 1970. The explanation of this paradox lies, in part, in the vagaries of Brazilian laboratories in reporting vaccine production. Virtually all other laboratories reported the numbers of doses produced in terms of 1 dose being equivalent to 0.01 ml of reconstituted vaccine. An ampoule containing the standard amount of 0.2 ml or 0.25 ml was reported as 20 or 25 doses. When the conventional scarification technique had been used, this correspondence between the number of doses and the size of the ampoule was approximately correct, but with the introduction of the jet injector and the bifurcated needle many more persons could be vaccinated with the same amount of vaccine. Notwithstanding this development, producers elsewhere continued to report production on the basis of 0.01 ml of reconstituted vaccine being equivalent to 1 dose. The Oswaldo Cruz Institute, however, produced

vaccine in ampoules which, when reconstituted, contained 0.35 ml and 1.0 ml and which were designated, respectively, as 100 and 400 doses. Similar practices were followed in other Brazilian laboratories. Not only was reported production inflated by a factor of 3-4 compared with that of other laboratories, but wastage in the field was greater because of the larger ampoules.

The extensive use of a consistently inferior vaccine in Brazil throughout most of the period of the programme was compensated for by the closely supervised vaccination campaign. Had vaccines of comparable quality been employed in most other programmes, the transmission of smallpox would not have been interrupted.

## CONCLUSIONS

Eradication was finally achieved in Brazil, and in South America as a whole, in April 1971, nearly 5 years after the promulgation of the federal decree of 31 August 1966 which set the programme in motion in Brazil. However, as in many other countries, the progress achieved by the programme was erratic and the chances of success were in doubt as late as 1970.

Several factors may be seen, in retrospect, to have been essential to the achievement of eradication. In the initial stages, Dr da Silva's organizational talents, tested during years of work in malaria eradication, served to establish an effective administrative structure. Thereafter, observations made during field investigation, assessment of vaccine coverage and surveillance altered strategy and provided a necessary stimulus to government at critical moments. At an early stage, field investigation of an outbreak in a town whose inhabitants were said to have been well vaccinated dramatically pointed up the need for routine assessment of vaccination coverage and take rates. An assessment programme,

### The Precarious Status of the Programme in Brazil, February 1970

Extracts from a letter from D. A. Henderson to Dr Charles Williams, Deputy Director of PAHO, dated 10 February 1970:

"It seems quite clear that the situation is not good. Both Drs Candau [Director-General of WHO] and Horwitz [Director of PAHO] were very concerned and had communicated this to me during the EB [WHO Executive Board meeting, held in January]...

"The visit of Dr Wehrle [a WHO consultant] originally had been thought of as an effort to strengthen surveillance as, from the reports, it seemed like one additional modest push in the right direction could put the programme over the top... however, surveillance, such as it is, is collapsing along with a good many other things; much had been said about the development of the network of reporting centres but, in fact, very little had been done and even in those states where it was said to be well-established, this was anything but the case.

"Candidly, I'm afraid that WHO is in no small way at fault. Despite Brazil having been recognized as the No. 1 problem, from the beginning, Connaught Laboratories' consultants have been dispatched from Cuba to Mexico to Peru with an occasional brief stop at the one laboratory which supplies 80-90% of all vaccine to the one endemic country... Parenthetically, the Brazilian laboratories are now the *only* producing laboratories in endemic countries manufacturing sub-standard vaccine. Money has been directed to smallpox projects in any number of countries (most recently Venezuela!) when, in fact, the real need is Brazil plus the need to keep a watchful eye on Paraguay and northern Argentina. Now even the man for this latter function has been terminated, so I have just learned...

"I would hope we could chart some alternative future course at the earliest possible time... some sort of reasonably high level discussions in Brazil should be arranged at the earliest possible time."

using a sample survey technique, was quickly developed; this evolved into one of the most effective and thorough of any smallpox eradication programme.

The weekly surveillance bulletin (the *Boletim semanal*), launched in May 1967, documented the programme's progress or setbacks for staff at all levels and communicated information on new developments and procedures to everyone concerned. When a perceptive health secretary assigned 3 surveillance officers for surveillance-containment functions and these workers promptly discovered an additional 50 cases for each case investigated, the weekly bulletin broadcast the news of what seemed to be an alarming epidemic. The press, the Minister of Health and even the President took a new interest in the programme. By the middle of 1970, it achieved its full momentum.

Whether transmission could have been interrupted without the extensive vaccination programme but with effective surveillance-containment measures is an unanswerable question. Because the disease occurred only in the mild variola minor form, there was

less of a stimulus for vaccination, and thus vaccinal immunity in Brazil in 1967 was probably among the lowest in the endemic countries. Transmission was successfully interrupted in Paraná State by surveillance-containment measures alone, but Paraná was one of the more prosperous states with a more extensive health infrastructure than those in the north-east and in the Amazon area.

Whatever the shortcomings of the programme, eradication was achieved in somewhat less than 5 years in a population of nearly 100 million people. In the course of the programme, a large cadre of young health staff obtained practical training and experience in epidemiology, which they were subsequently to apply to other health problems during service in Brazil and in international health organizations. The household probability survey, used in assessment, was later adapted for similar use in other programmes, ranging from family planning to poliomyelitis; and the weekly smallpox surveillance bulletin has since become Brazil's weekly communicable disease report.

### INTRODUCTION

In 1967, smallpox was endemic in 5 Asian countries, whose total population amounted to 769 million. Four of these countries—Afghanistan, India, Nepal and Pakistan—were contiguous, sharing long borders, which travellers (including people infected with smallpox) crossed with relative freedom. However, the fifth country, Indonesia (population, 112 million), lay some 2000 kilometres south-east of the nearest endemic area on the continent—East Pakistan (after 1970, Bangladesh). Comparatively few people travelled between Indonesia and the other 4 countries. Thus, it seemed logical and opportune to concentrate resources and energies initially in Indonesia in the expectation that on becoming free of smallpox, the country would not be seriously threatened by importations (*Wkly epidem. rec.*, 1969a). WHO resources committed to Indonesia could then be shifted to other programmes in Asia. The fact that smallpox

transmission had once been interrupted in Indonesia, immediately before the Second World War, added strength to the belief that the objective could be attained.

As had been hoped, Indonesia was the first of the 5 Asian countries to become free of smallpox. The programme began there in June 1968; the last known case occurred little more than 3½ years later, on 23 January 1972. The achievement of eradication so quickly in such a large and populous country was both a surprise and a stimulus (and to some degree an embarrassment) to health staff in Bangladesh, India and Pakistan, whose programmes had by then been in progress for a decade. That this feat had been accomplished with little more than US\$1 million in international assistance made it even more notable.

Success was not easily achieved in the Indonesian programme. Smallpox was tenacious and spread readily even among populations with exceptionally high levels of vaccinal immunity—a marked contrast to the

behaviour of the disease in most endemic countries of Africa and the Americas. Full credit for the achievement is due to an imaginative group of Indonesian and WHO staff, who conceived and evolved effective strategies that were later adapted for use in other parts of the world and proved vital to the interruption of smallpox transmission in the Indian subcontinent. Among Indonesia's contributions to global eradication were the concept of a special programme involving a village-by-village search for cases, the introduction of a reward system for anyone reporting a case of smallpox and the development of the widely used WHO smallpox recognition card (see Chapter 10, Plates 10.29, 10.30).

A number of papers were prepared describing selected aspects of the Indonesian programme, although a book would have been warranted to recount the whole gamut of activities. There was little time available to attempt a detailed narration, however. When eradication was certified in 1973, experienced staff were urgently needed in other countries; key Indonesian staff and the WHO advisers who had been assigned there responded promptly and, in so doing, contributed to the record of achievement compiled in India, Bangladesh and Ethiopia.

### THE DECISION TO BEGIN THE PROGRAMME

Originally it had been hoped that the campaign in Indonesia might begin during the first year of the Intensified Smallpox Eradication Programme but its start was delayed until June 1968. In part, this stemmed from doubt and inertia in the WHO Regional Office for South-East Asia in New Delhi, India. The then Regional Director believed that the health resources in the countries of the region were too inadequate to permit eradication to be realized. He frankly and publicly stated his view that the World Health Assembly's decision to undertake global eradication was ill-advised, and consequently offered little support to the programme. Likewise, the Regional Adviser for Communicable Diseases, the senior technical officer, took little interest. A memorandum of 10 October 1967 from Henderson to his superior in WHO Headquarters, Dr Karel Raška, the Director of the Division of Communicable Diseases, summarized the situation prevailing during much of that year:

"In December [1966] and April [1967], the considerable importance of an early visit to Indonesia to assess Government interest and capability to undertake [smallpox eradication] had been agreed by [the Regional Adviser for Communicable Diseases] and myself. No visit has yet been undertaken and none is contemplated until possibly November. In fact, I gather there was no correspondence with Indonesia on the question of [eradication] until July... No solutions are proposed; no possible courses of action are outlined."

Subordinate to the regional adviser and ostensibly responsible for providing assistance to countries in developing smallpox eradication programmes was a 2-man inter-country advisory team for epidemiology whose duties then encompassed a range of different activities. During his visit to New Delhi, Henderson had met the team, which had exhibited both an interest and a desire to proceed rapidly in the development of WHO smallpox eradication programmes. Subsequent communication with them by mail proved difficult. All correspondence relating to smallpox eradication between WHO Headquarters and the regional office, as well as between the countries and the regional office, was routed first to the regional adviser. Seldom was it passed to the inter-country team. By the end of November 1967, the intercountry team had been permitted to make only two brief visits, to Afghanistan and Nepal, the only countries in the region in which WHO-supported smallpox eradication programmes were then in progress. In the autumn of 1967, one of the team's members, Dr Jacobus Keja, prepared a draft plan of operations for Indonesia but was denied permission to visit the country to discuss the plan.

The lack of activity in the South-East Asia Region and its failure to obligate smallpox eradication funds allotted for the calendar year led to important financial ramifications in the global programme as a whole. When the budget for smallpox eradication for 1967 had been approved by the Nineteenth World Health Assembly, several countries had expressed the view that an allotment of US\$2.4 million for the first year was too large and proposed instead that a sum of US\$1 million should be provided (see Chapter 9). The larger allocation was eventually agreed on, but only after assurances had been given by the Director-General that the full amount was needed and could be spent. In the American and Eastern Mediterranean Re-

gions, activities were progressing sufficiently well to ensure that the funds allotted to them would be obligated. However, US\$806 000 had been assigned to the South-East Asia Region and little of it had been spent. If these funds were not obligated by the end of the year, not only would they be lost to the programme, but the possibility of questions arising at the next World Health Assembly could be foreseen, conceivably resulting in reductions in subsequent budgets for smallpox eradication. Because of this problem, the Regional Director finally agreed, in November 1967, that the intercountry team should discontinue its other activities and assume primary responsibility for smallpox eradication under a higher-level regional office official, the Assistant Director for Health Services. With this administrative change, the development of a programme in the region became feasible.

Three other events occurred during the autumn of 1967 which were to alter significantly the possibilities for eradication in the South-East Asia Region and in Indonesia in particular. A new WHO Regional Director, Dr Herat Gunaratne, was nominated in September 1967 and took office in February 1968. As President of the Twentieth World Health Assembly, in May 1967, Dr Gunaratne (a former Director-General of Health Services in the smallpox-free country of Sri Lanka) had stated categorically that the

eradication of smallpox was wholly achievable, that it was simply a matter of will and determination. As testimony to this belief, he offered his own considerable enthusiasm and support for the programme.

The second event was the appointment in November 1967 of Dr Julie Sulianti Saroso to the post of Director-General for the Control and Prevention of Communicable Diseases in the Indonesian Ministry of Health. This decisive and energetic woman was determined to revivify a discouraged and listless health staff who had received little pay for more than 4 years because of a decision by the previous government that health care costs should be borne primarily by private individuals. Although the health staff were expected to supplement meagre salaries through charges for their services, few were successful in obtaining even subsistence wages. Dr Sulianti promptly asked for help from WHO. The regional office decided that Dr Keja should visit Indonesia en route to an intercountry seminar on smallpox, due to begin in Bangkok on 11 December. He arrived in Jakarta on 7 December 1967.

The third event was the development of epidemic smallpox, beginning in August 1967 with an outbreak in the capital city, Jakarta. By November, more than 50 cases a week were being reported (Fig. 13.1).

With Dr Sulianti, Dr Keja at once decided to carry out a sample survey of the city to

Fig. 13.1. Jakarta Municipality: number of reported cases of smallpox, by 4-week intervals, 1963-1967.

BY COURTESY OF N. KUMARA RAI

**Plate 13.1.** Several national and intercountry seminars on smallpox eradication were held in Indonesia. At the concluding seminar, in September 1972, Julie Sultanti Saroso, Director-General for the Control and Prevention of Communicable Diseases, presented an award to Nyoman Kumara Rai, who had directed the Indonesian Programme since April. Standing behind the Director-General are 2 WHO advisers, G.G.O. Cuboni (*far left*) and W. L. R. Emmet.

assess vaccinal immunity—the first of many such surveys to be conducted during the global programme. For this survey, 20 field staff from the smallpox and malaria programmes were selected and trained. Each examined 200 children for vaccination scars and the facial pockmarks of smallpox in a house-to-house survey beginning from randomly selected points in the city. In only 4 days, the survey had been completed and the results analysed. From the survey and a review of other available data, it was apparent that there were major problems:

(1) Reporting was incomplete. In all, 1265 cases and 413 deaths had been recorded during 1967, but because so many cases were found during the survey the actual number of cases was thought to be at least twice this figure.

(2) The number of vaccinations given was insufficient to sustain immunity. Jakarta Municipality's 49 vaccinators had performed 384 000 vaccinations in 1967, but only 35 295 (9.2%) had been primary vaccinations. In a

population of 1.4 million, with a birth rate of 40 per 1000, it was calculated that 56 000 primary vaccinations would be required annually simply to protect newborn infants.

(3) The proportion of successful primary vaccinations was unsatisfactory. Take rates of only 60–80% were observed, a phenomenon attributed to the use of vaccine of lower than acceptable titre as well as unsatisfactory vaccination technique.

However, vaccinal immunity, though still not adequate, was found to be far higher than expected. Vaccination scars were seen in 90% of children aged 5–14 years, in 75% of those aged 1–4 years, and in 45% of infants aged less than 1 year. Nevertheless, the situation was clearly disturbing. Smallpox was spreading rapidly throughout a reasonably well vaccinated urban population; the vaccination campaign was lagging and was further compromised by the use of substandard vaccine; extension of the epidemic into less well vaccinated rural areas was only a matter of time. A programme for smallpox eradication

<sup>a</sup> Population estimates as recorded in 1968. United Nations (1985) data show a total population of 114 798 000 for Indonesia in 1968.

was urgently needed and indeed its development proceeded rapidly.

The above-mentioned WHO intercountry smallpox seminar in Bangkok, which, by lucky timing, took place immediately after the Jakarta survey, provided the opportunity for a draft plan of operations to be finalized. Indonesia's representative, Dr Ignatio Setiady, Director of Communicable Disease Control, met Henderson and Dr Keja, and using the latter's earlier prepared draft, worked out a plan for the programme and estimated the cost involved and the assistance required.

A critical problem, and one that was never really solved, was that of providing Indonesian

staff with high enough salaries to permit them to work virtually full time. Vaccinators, for example, were then receiving the equivalent of US\$2 a month, which was insufficient to buy food for themselves, let alone for their families. WHO's resources could not deal with the situation in its entirety. Despite this problem, it was apparent from the survey that somehow a large proportion of the population was being vaccinated. With hope rather than confidence that the vaccinators would continue to function, it was agreed that supplementary WHO funds would be provided to a small number of senior Indonesian staff to permit them to carry out full-time supervisory functions; other personnel would necessarily work only part time, and field operations would have to take this into account. WHO also agreed to provide a medical officer and to purchase various items, including 15 vehicles, 135 motor cycles, 1550 bicycles, 23 refrigerators and vaccine production equipment. By the end of December, funds for equipment and supplies had been obligated. Less than a month later, on 24 January 1968, Indonesia's Minister of Health signed a formal agreement with WHO authorizing the programme. Field operations were scheduled to begin in June 1968.

#### DEMOGRAPHY AND GEOGRAPHY OF INDONESIA AND ITS HISTORY OF SMALLPOX CONTROL

The country's demographic and geographical features, as well as its remarkable history of smallpox control, were determining factors in the development and progress of the programme.

The Indonesian archipelago, extending over more than 4800 kilometres, consists of

Plate 13.2. Ignatio F. Setiady (b. 1929), Director of Communicable Disease Control, at the 1967 WHO seminar in Bangkok, Thailand, where plans for the Indonesian programme were worked out.

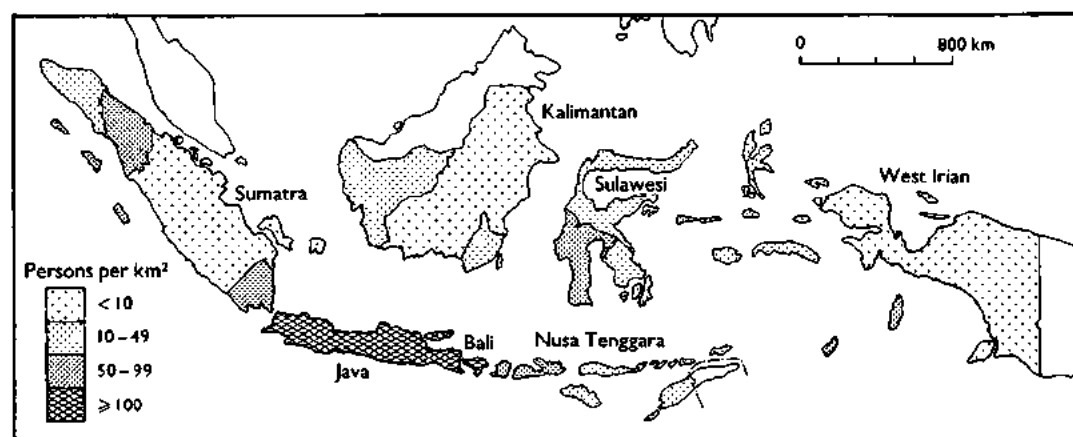

Fig. 13.2. Indonesia: population density, 1968.

some 13 000 islands, of which 3000 are inhabited. In 1968, 66% of the country's 115 million people lived on the densely populated islands of Java and adjacent Bali (Fig. 13.2; Table 13.1). Most of them (83%) lived in localities with 5000 or fewer inhabitants or in rural areas. However, it was estimated that fully 60% of the population could be reached by motorized vehicle, 20% by boat and 20% on foot or by bicycle.

For administrative purposes, Indonesia in 1968 was divided into 26 provinces, which were subdivided into 288 regencies and municipalities (Table 13.2), consisting of 3203 subdistricts. The smallest administrative unit was the village. The size of the population in these administrative divisions varied considerably from one area to another.

Although organized vaccination campaigns in Java dated back to 1856, an extraordinarily effective campaign was begun in the 1920s which was successful in interrupting smallpox transmission as early as 1936 (Table 13.3).

Of the 21 cases recorded between 1937 and 1940, 7 were found to be importations and the others were suspected to be either importations or mistaken diagnoses (Polak, 1968). The Second World War intervened and morbidity reporting ceased. After the war, no

cases are known to have occurred in Indonesia until May 1947. The first cases were reported from the Riau Islands, adjacent to Malaysia, in which smallpox was then endemic. Over the next few years, the disease swept eastwards across the western and central islands of the archipelago, 99 016 cases being reported in 1950. However, smallpox did not spread beyond Sulawesi and West Nusa Tenggara to the numerous but more sparsely populated islands to the east—East Nusa Tenggara, Maluku and West Irian (Fig. 13.3).

The methodology employed in the vaccination campaign of the 1920s and 1930s is of interest, since the structure and many of the operational components of the campaign still existed in 1968 (Polak, 1968), although the number of staff had diminished and the

quality of performance was poorer. A trained vaccinator was assigned a vaccination district of about 100 000 persons. Under the supervision of a medical officer who was responsible for several regencies, he travelled by bicycle and on foot through his assigned district on a strictly prescribed schedule. During each 3-month period, he devoted 8 weeks to primary vaccination and 5 weeks to revaccination. Infants were brought to designated collecting points not more than 6 kilometres from their homes and up to 150 were vaccinated daily. In the case of revaccination, up to 500 persons were dealt with each day. When outbreaks occurred, intensive programmes of vaccination were conducted in the areas infected. Most vaccinators used liquid vaccine, produced by the government-owned quasi-independent Lymph Institute in Bandung (Biofarma), which had opened in 1891. In the more remote districts, a remarkably stable, room-dried and vacuum-sealed vaccine was used which had been first produced in 1926 (Otten, 1932).

In the systematic vaccination campaign, resumed after the Second World War, both liquid and room-dried vaccines and eventually some freeze-dried vaccine were used. High

inflation rates and the drastic reduction of salaries of government health staff forced vaccinators and other personnel to take additional jobs. Periodic *ad hoc* mass vaccination campaigns were also conducted, financed by local merchants and village organizations. The numbers of vaccinations reported by vaccinators in Java from 1963 to 1967 indicate the extent of activity (Table 13.4).

In all, 15–25% of the population in the different provinces were reported to have been vaccinated annually by the special vaccinators. Of the total number of vaccinations, 10–15% were recorded as primary vaccinations. In addition, vaccinations were performed in local clinics and maternal and child health units; these were not included in the totals but their number was thought to be large. On the basis of this information, it was difficult to guess the probable extent of vaccinal immunity. Not only were the reports of vaccinations performed considered to be suspect, but primary take rates were reported to range from 33% to 88%. Both high and low rates were recorded during the use of each of the 3 forms of vaccine then being produced: liquid, room-dried, and a small quantity of freeze-dried vaccine. Be-

cause refrigeration facilities were limited, low primary take rates with the thermolabile liquid vaccine were understandable. The low take rates with the more stable freeze-dried and room-dried vaccines reflected, in part, the low potency of some batches; moreover, none of the dried vaccine was kept under refrigeration, since the manufacturer claimed that it retained its potency at room temperature for 18 months. Although a few batches attained this degree of stability, most did not.

Special mass vaccination campaigns had been conducted in Jakarta in 1962-1963, in East Java in 1964, in West Java in 1965 and in Central Java beginning in the autumn of 1966. The campaigns were not well supervised or well coordinated and were chronically short of funds to pay vaccinators and to purchase vaccines from the Biofarma laboratory.

Despite the apparently questionable efficacy of the campaign, vaccinal immunity in Java proved to be surprisingly high, although the level of immunity varied widely from one locality to another. Sample cluster surveys, similar to the one conducted by Dr Keja in Jakarta in December 1967, were carried out in January and February 1968 throughout Java. In all, 56 619 children under 15 years of age were surveyed. All the children were examined to determine whether facial pockmarks were present and whether or not they had a vaccination scar. From these studies, an estimate of the level of vaccinal immunity was

obtained (Table 13.5), as well as an approximation of the completeness of smallpox notifications.

Less than one-quarter of all the children were considered to be fully susceptible to the disease. Only 807 (1%) had facial pockmarks characteristic of smallpox. Since persons less than 15 years of age constituted approximately half the population and since only a small proportion of those older than 15 were fully susceptible, it was assumed that not more than perhaps 10-15% of the total population were then susceptible to smallpox. Not surprisingly, at that time more than 75% of smallpox cases were reported to be occurring among children under 15 years of age (Table 13.6) and upwards of 80% of cases occurred among those without a vaccination scar.

#### SMALLPOX INCIDENCE, 1963-1967

National data for smallpox prior to 1963 provide little indication as to the incidence or

<sup>a</sup> No cases were reported from Maluku, East Nusa Tenggara or West Irian during this period.

geographical distribution of the disease. Not only did villages and regencies fail to report to provincial authorities, but many provincial administrations submitted no reports to the national authorities. The number of cases officially recorded at the national level varied from 1000 to 10 000 during the period 1952-1962. Better data are available for the years 1963-1967, because smallpox control staff visited each of the provinces during 1968 to compile provincial data from previous years in order to obtain baseline information. In 1963, 17 431 cases were recorded, of which all but 3658 were from West Java (Table 13.7). The most complete data available pertain to the years 1965-1967, and these show a wider dispersion of smallpox throughout the central and western islands of Indonesia.

Major epidemics were reported in 2 areas during the period 1965-1967 (Fig. 13.4). In 1965, East Java reported 36 120 of the 56 359 cases recorded in Indonesia and this epidemic was followed in 1966 by one in neighbouring West Nusa Tenggara. Central and South Kalimantan experienced epidemics in 1965, which gradually subsided over the next 2 years without a planned vaccination campaign. Other provinces of Indonesia also reported significant numbers of cases, but because of inadequate reporting few conclu-

sions can be drawn about the comparative magnitude of the smallpox problem in these areas. That reporting was seriously deficient was shown in the January 1968 survey in Java. In this survey, estimates of recent smallpox incidence were derived from the prevalence of facial pockmarks. The survey revealed that, at most, 10% of all cases were actually being reported. Thus, it was calculated that more than 100 000 cases had occurred in 1967 in Java alone. Reporting from the other islands, in which the health resources were fewer, was much less complete than in Java.

#### ORGANIZATION OF THE PROGRAMME, JANUARY-JUNE 1968

Dr Sulianti lost no time in setting the eradication programme in motion. As a first step she changed a meeting on tuberculosis vaccination scheduled for February 1968 into a planning seminar for smallpox eradication. It was to be the first of a series of annual national meetings which reviewed the programme's progress and established specific plans and targets for the succeeding year. Those attending included Dr Sulianti's staff; senior health officials from the provinces, regencies and municipalities; directors of

### Estimates of the Completeness of Case Notification

It was common knowledge that many cases of smallpox were not reported to the health authorities but the general belief was that the true figure was not more than perhaps 2-3 times the number of recorded cases. The fact that 10 067 cases were known in 1967 to have occurred that year was of concern to health officials but it was not cause for real alarm. Dr Keja suspected that underreporting was a much more serious problem and performed a number of simple calculations to estimate its magnitude. The 1968 survey teams had found that 39 out of 8636 children under 1 year of age had the characteristic facial pockmarks and thus had contracted smallpox during the preceding year, 1967. Extrapolating from this rate of 4.5 cases per 1000 to the entire population of children under 1 year (2 457 000), Dr Keja arrived at a figure of 11 056 cases. However, since Indonesian data showed that 40% in this age group died of smallpox, he reasoned that the actual number who had had smallpox was 1.67 times larger. Making further corrections to allow for the fact that at least 10% survived without recognizable pockmarks, and calculating that those under 1 year of age accounted for not more than one-fifth of all smallpox cases, he estimated that at least 100 000 cases of smallpox had occurred during 1967 in Java alone, or 10 times more than the number recorded. The numbers in the survey were small and the method of estimation, although unsophisticated in statistical terms, was understandable to non-technical people. The Minister of Health was incredulous and asked other statisticians to examine the data. All of Dr Keja's assumptions served to understate the magnitude of the problem. Case-fatality rates among infants under 1 year were nearer 50% than 40%; the proportion of those surviving without recognizable pockmarks was closer to 35% than 10%; and the proportion of cases in Indonesia among those under 1 year was actually 14% rather than 20%. Finally, Dr Keja had made no effort to correct the estimate to reflect the fact that the children who were examined were all less than 1 year of age and thus, on average, had actually been exposed to smallpox only over a 6-month period. His decision to develop a conservative but understandable estimate had been deliberate. The figure of 100 000 cases was impressive in itself. When Indonesian statisticians independently made their own estimates, they calculated that the number of cases had more likely been in the range of 200 000-500 000. The Minister was persuaded that smallpox was indeed a problem of high priority in Indonesia.

maternal and child health, school health and malaria control programmes; and representatives from the armed forces, the Ministry of Home Affairs and the Central Bureau of Statistics. The seminar represented a laudable effort to involve a wide range of civil and military authorities in the programme although, in fact, few of those present were to make significant contributions until late in its course.

It was decided to launch the programme in June 1968 in Java and Bali, in which 66% of the population lived, and to extend it to the outer islands a year later. Additional vaccinators would be appointed for each subdistrict (40 000-50 000 population), which would more than double the number then in the field. However, they would work only part time, as did the others, because their pay remained low. A supervisor would be ap-

pointed for each regency (500 000-1 000 000 inhabitants) and additional supervisory staff would be provided at provincial and national levels. In each of the 90 regencies and the 6 provinces, a "fire-fighting" team of 3 or 4 persons would be formed from existing staff specifically to contain outbreaks.

Because the vast majority of cases were occurring among the unvaccinated, vaccinators were instructed to concentrate on primary vaccination. The maternal and child health centres were directed to vaccinate all infants attending clinics (estimated to represent about 40% of the total number of infants) and the school health services to vaccinate all schoolchildren (corresponding to about 50% of all children of school age). The newly developed bifurcated needles and the multiple puncture technique of vaccination would be employed by all vaccinators

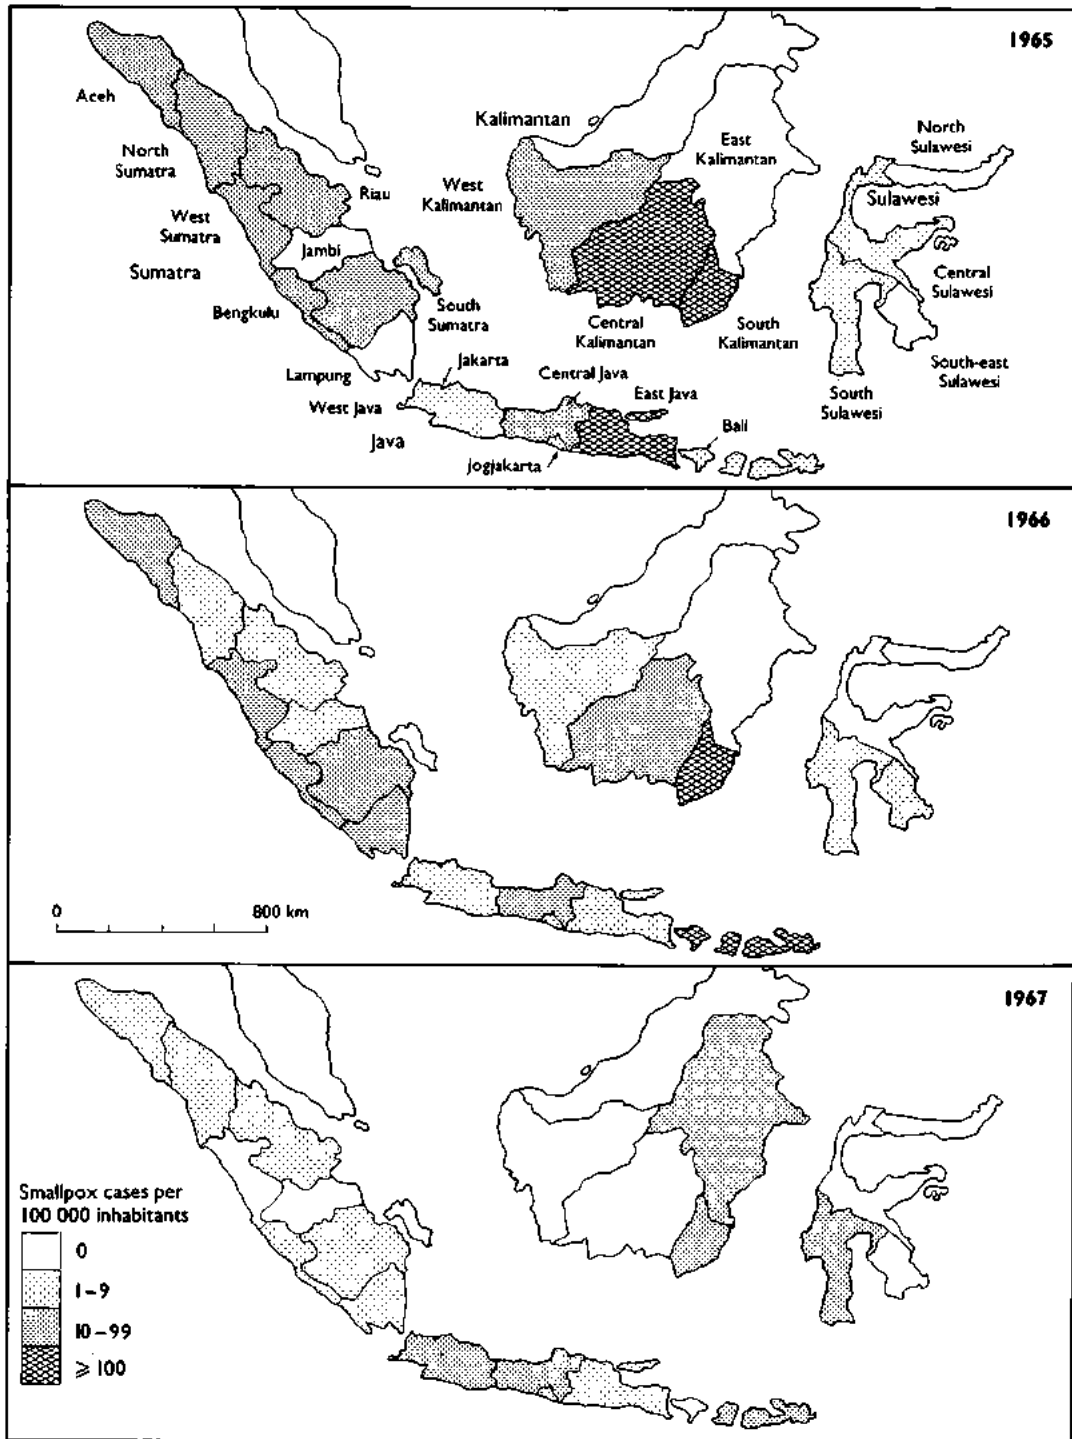

Fig. 13.4. Indonesia: number of reported cases of smallpox per 100 000 inhabitants, 1965-1967.

except the members of national surveillance-containment teams, who would use jet injectors supplied by WHO. It was agreed that only freeze-dried vaccine would be employed, that

cold-storage depots would be established at national, provincial and regency levels, and that each batch of vaccine produced by the Biofarma laboratory would be tested by WHO

laboratories and released for use only after certification that it met WHO standards of potency, stability and bacterial content.

In support of the programme, WHO eventually provided a total of US\$1 300 363 to cover the purchase of supplies and equipment, local costs and staff costs (Tables 13.8 and 13.9); it also provided for the acquisition of 4.1 million doses of vaccine. Indonesia's expenditure amounted to US\$3 600 000. The total outlay was equivalent to just over US\$0.04 per head of population.

The central staff initially consisted of 4 medical officers (later increased to 8), 7 health inspectors (later 10) and 12 administrative staff. A WHO medical officer was assigned throughout the programme (Dr M. F. Polak, July 1968-January 1969; Dr Reinhard Lindner, January 1969-July 1971; Dr G. G. O. Cuboni, May 1971-1973), and an operations officer, Mr William Emmet, was appointed in August 1970. WHO short-term consultants assisted for a period of approximately 24 man-months.

The programme was conducted by a specially created Smallpox Eradication Unit in the Directorate of Epidemic Control under the direction of a motivated and committed physician, Dr P. A. Koswara. This unit, in turn, reported to Dr Sulianti. At the provincial level, there was a smallpox eradication programme section, also headed by a full-time medical officer. At the regency/municipality

level, the responsibility for the programme rested with a medical officer assisted by an experienced senior sanitarian and one or more assistant supervisory sanitarians.

#### THE EARLY STAGES OF THE PROGRAMME, JUNE 1968-JULY 1969

At the beginning of the programme, pre-occupation with the vaccination component was perhaps inevitable. This approach had proved effective in the late 1930s, despite reliance on the use of thermolabile glycerolated vaccine in the main islands and a variably potent but stable room-dried vaccine in more distant areas. National and WHO programme staff believed that with an already high level of immunity, the increased number of vaccinators, using a freeze-dried vaccine of assured potency, should be able to find and vaccinate the comparatively small proportion of susceptible people and so interrupt transmission rapidly. As would prove true in other countries of Asia, this strategy did not work.

Throughout Indonesia, 3130 vaccinators—approximately 1 for each subdistrict—and 324 regency supervisors conducted the programme. On average, this amounted to 1 vaccinator for every 39 000 persons, the ratio ranging from 1 to 9000 in sparsely inhabited areas to 1 to 50 000 or more in densely populated regions. The pre-war procedure, according to which vaccinators visited each

R. LINDNER 1971

**Plate 13.3.** Petrus Aswin Koswara (1931–1974), directed the national programme until April 1972. Standing at centre, he is speaking with Dr Hasan Anoez, Provincial Medical Officer in South Sulawesi, and D.A. Henderson in 1971.

village 4 times a year to give primary vaccinations and one-third of all villages to perform revaccinations, was modified to emphasize primary vaccination. During 8 weeks of each quarter, vaccinators were instructed to visit all villages to give primary vaccination to all preschool children (up to 4 years of age), including newborn infants. During the remaining 5 weeks, they were instructed to visit one-quarter of all villages to vaccinate or revaccinate all children aged 5–14 years. The programme was modified in Bali, in which vaccination was entrusted to malaria surveillance workers. If well executed, this intensified campaign would have ensured, within 1 year, vaccinal immunity in nearly all children from birth to 14 years of age, the age group in which most cases were occurring.

The problems of vaccine supply and quality were gradually resolved over a period of 18 months. Biofarma ceased production of the liquid and room-dried vaccines and began to produce freeze-dried vaccine only. UNICEF provided additional vaccine production equipment and WHO recruited consultant assistance for the laboratory. Better methods of quality control, as well as improved pro-

duction methods, were instituted. By the end of 1968, the quality of the freeze-dried vaccine began to meet accepted WHO standards and, during 1969, the laboratory began to produce sufficient vaccine to meet Indonesia's needs. In the meantime, vaccine donated to WHO by New Zealand, Thailand, the USSR and the USA augmented the supply. National and provincial cold-storage depots were already available; WHO provided additional refrigerators for use at the regency level. To simplify procurement and distribution, the national health authorities decided to purchase all vaccine from Biofarma with national funds and to distribute it without charge to provincial health departments, which, in turn, were to distribute the vaccine to regencies.

Not surprisingly, a host of problems arose in a programme which was to be so greatly strengthened and executed in such a large population with only 6 months of preliminary planning and organization. One by one, these difficulties were resolved. To cite a few of the more important: deliveries of vehicles, bicycles and other items transported by sea were delayed by months because of customs

BY COURTESY OF D. A. HENDERSON

**Plate 13.4.** Biofarma laboratory, Bandung. (A) which produced smallpox vaccine for the programme. As late as 1968, room-dried vaccine was still being prepared by the procedure introduced by Otten in 1926. The vaccine pulp was dried in desiccators (B), after which it was put in vials which were sealed under vacuum (C). The vaccine was remarkably heat-stable but difficult to produce and was often contaminated with bacteria.

clearance formalities; government fiscal procedures were cumbersome and payments for vaccine to Biofarma were held up, resulting in the periodic cessation of production in late 1968 and 1969; payments to staff were similarly interrupted from time to time, with a consequent suspension of work; the recording of cases and transmission of data were seriously deficient; and effective supervision at the beginning of the programme was minimal. All these problems had to be dealt with more or less simultaneously and all persisted to some degree or recurred throughout most of the programme.

For the vaccination campaign, it was decided to establish an annual target for primary vaccinations equivalent to 6% of the population and one for revaccinations equivalent to 30% of the population. It was an unrealistic expectation, given that the vaccinators worked only part time and that the supervision and planning of vaccinator tour schedules were marred by lack of experience. Vaccinators on average performed only 20-80 vaccinations per day, of which between 2 and 20 were primary vaccinations. The programme never met its targets, although it began to approach them in 1970 (Table 13.10). A repeat stratified cluster sample survey in June 1969, similar to that performed in January 1968, showed no significant change in the proportion of susceptible persons (*Wkly epidem. rec.*, 1969c).

The plan had called for "fire-fighting teams" at regency level to contain outbreaks, but few of the regency teams functioned well—and most of them not at all—because of lack of interest and motivation. Vaccination to control outbreaks was neither thorough nor systematic; the sources of cases were not traced, and few of the locales of outbreaks were revisited to ensure that transmission had been stopped.

Indonesia, so densely populated, had seemed to be an ideal place to use jet injectors

in outbreak containment. The injectors were provided by WHO and, in August 1968, a consultant was recruited to train special vaccination teams in their use and maintenance. As was true in many other areas, the concept was attractive in theory but disappointing in practice. Except in urban areas, the population was not accustomed to gathering in large numbers at collecting points, and unless they did so the considerable capacity of the injectors could not be realized. Maintenance and repair of the injectors and the logistics of providing a flow of spare parts proved to be formidable obstacles. Within a year, the jet injectors had been abandoned in favour of bifurcated needles. Not only did the latter yield far better results in comparison with the old vaccinostyle (as was revealed in a short trial in Ciloto, West Java) but they also proved to be considerably more economical in the use of vaccine. Beginning in March 1969, the bifurcated needle was accepted as the standard equipment for vaccination in the programme.

Improvement in the supervision and execution of the programme was needed at all levels and, to effect this, 13 "advance teams" (1 each in Jakarta, Jogjakarta and Bali, 2 in East Java and 4 each in West and Central Java) were established in January 1969. These teams provided a critical link in supervision between the national programme directorate and the regencies and were ultimately instrumental in instituting an effective surveillance-containment programme. They were given a month of special training and sent to the field. Each team was provided with a WHO vehicle and was headed by a physician who was able to work full time in the programme, thanks to a salary subsidy paid by WHO. The initial plan called for the teams to spend two-thirds of their time in surveillance and containment activities and one-third in improving the supervision of vaccinators.

<sup>a</sup> No cases were reported in Maluku, Bali, Nusa Tenggara or West Irian during this period.

Despite the chaotic beginning and the numerous problems, remarkable progress was recorded in some provinces (Table 13.11). East Java had experienced major epidemics in 1964 and 1965 and, in consequence, had conducted mass campaigns. However, the vaccination survey of December 1967–January 1968 (see Table 13.5) showed that vaccinal immunity was no better than in West Java and far lower than in Central Java despite the mass campaigns. In July 1968 a dynamic Provincial Director of Communicable Disease Control, Dr Bahrawi Wongso-kusomo, and his assistant, Dr Witjaksone Hardjotanojo, took charge of the programme in East Java and vowed that they would interrupt transmission before January 1969. Vaccination activities were intensified, but—more important—any outbreaks found were energetically contained. During the last 6 months of 1968, only 133 cases were detected in the entire province. Between January and June 1969, only 3 outbreaks occurred, each of which could be traced to importations from Central Java; all were well contained after discovery. It was a remarkable achievement, accomplished almost wholly with provincial resources.

In Jakarta, under the leadership of Dr Guno Wiseso, special teams equipped with jet injectors demonstrated the efficacy of the

outbreak-containment strategy. During a 3-month period, they investigated and contained 73 outbreaks, in which 217 cases had been reported (*Wkly epidem. rec.*, 1970a). The teams searched for additional cases, endeavoured to find the origins of the outbreaks and vaccinated the inhabitants of the affected administrative units (about 200 persons in each unit), as well as the people living in the 4 surrounding units. During these activities they discovered an additional 215 cases and vaccinated some 73 000 persons. A subsequent assessment revealed that smallpox transmission had ceased within 2 weeks of containment in two-thirds of the outbreaks (Table 13.12). Although these results would be considered poor by later standards, it was clear that outbreaks could, in fact, be quickly stopped.

No smallpox cases were reported in Bali or in the islands to the east after the programme began, and in February 1969 Jogjakarta recorded its last cases. By June 1969, smallpox in Central Java was being reported from only 4 of 35 regencies but West Java continued to report nearly 1000 cases per month. Meanwhile, the complement of vaccinators and supervisors in Java steadily increased and by June had more or less reached the numbers planned (Table 13.13). In Kalimantan, Sulawesi and Sumatra, the programmes did

not officially begin until July 1969, and thus all reports were considered to be suspect.

The number of cases reported in Indonesia between January and June 1969 amounted to 8789, a total not significantly different from the 8847 cases recorded during the same period in 1968. Although the staff believed that there was more complete reporting of cases, it was impossible to measure the extent of improvement. What was certain, however, was that reporting was still incomplete. The reporting of cases to the regency medical officer was the responsibility of village chiefs, but many chiefs completely neglected this task, even though they were aware that cases were occurring. Moreover, some regencies failed to report to the provinces, or, if they did, the reports were greatly delayed. In June, reports from almost one-quarter of all provinces in Java and Bali were overdue by a month or more. Reporting from other provinces was even more delayed and incomplete.

When the programme began, plans had been made for its assessment by a WHO-Indonesia team one year later. In June 1969, this was undertaken and recommendations were developed. The team was sharply polarized on the issue of mass vaccination. One group maintained that, with vaccinal immunity so high, the mass vaccination campaign could be said to have been completed already and that all efforts should be directed to surveillance and containment. A second group argued for a special campaign to move rapidly and systematically throughout the country to vaccinate the now very small proportion of people who had no vaccination scars.

A compromise was reached and the teams recommended that: (1) special programmes should be mounted to deal with the backlog of unvaccinated children under 15 years of age in Jakarta and West and Central Java (the number was estimated to be 3.3 million, or 16.6% of a population of 19.9 million children); and (2) surveillance should be strengthened through improved reporting by village chiefs and other health staff, and more active outbreak containment by the special "fire-fighting" and advance teams. It was recognized that the backlog vaccination campaigns would tax, and perhaps overstrain, available government resources, but the campaign was accepted as a component of the strategy.

### THE STRATEGY CHANGES, JULY 1969

The resources available did not permit the implementation of backlog vaccination campaigns throughout the whole of Java, and so priorities were defined. In East Java and the islands to the east, in which transmission had been interrupted, efforts were to be directed solely to the early detection and containment of imported cases. In Central Java, lying immediately to the west, smallpox incidence was declining and prospects for the early interruption of transmission appeared good. Thus, the decision was made for vaccination teams (called "backlog-fighting teams") to begin work in the eastern regencies of Central Java and to move westward in the expectation that smallpox would progressively disappear in an east-to-west direction. Given the prob-

Fig. 13.5. Central Java: number of reported cases of smallpox, by month, 1968–1970.

ability that the situation in West Java would soon follow the same course, backlog-fighting teams were scheduled to commence operations in the province's 7 easternmost regencies.

As the backlog-fighting teams began vaccination in Central Java, the 4 provincial surveillance teams started work in the northwest, where smallpox incidence was the highest. Directed by a capable epidemiologist, Dr P. R. Arbani, these teams concentrated entirely on case detection and outbreak containment. Gradually they extended the scope of their operations to include the whole province. The number of cases in Central Java declined dramatically (Fig. 13.5). In December only 31 cases were detected, and by May 1970 the last case had occurred. The advance teams had performed only 54 000 containment vaccinations, a small fraction of the 5 million vaccinations which were being given annually in the province.

West Java presented a more formidable problem. Provincial supervision had been inadequate for many years and this was reflected in the low levels of vaccinal immunity throughout the province. During the first half of 1969, an average of almost 250 cases had been reported weekly—in a province whose notification system was the poor-

est in Java. In July, 4 special teams, each consisting of 5 vaccinators and a team leader, were recruited for each of the 7 regencies bordering on Central Java (Koswara in WHO/SE/71.30). As in Central Java, the teams proceeded house by house and village by village, performing primary vaccinations and containing any outbreaks that were found.

By October 1969, it became apparent that smallpox transmission was continuing in West Java, even in regencies in which backlog fighting had been completed. Although the teams were instructed to intensify surveillance–containment activities, few did so. In one regency, Tjirebon, in which no such activities had been conducted (*Wkly epidem. rec.*, 1970a), a WHO adviser was assigned to undertake surveillance–containment activities only. National staff supervised combined surveillance–containment and vaccination programmes in 3 other regencies, including Bandung, in which smallpox incidence remained high. Two months later, in December, a main focus of smallpox in the province was found to be yet another regency, Bogor, in which so far no work was in progress. Resources were all but exhausted and only a single team could be assigned there to conduct a surveillance–containment programme.

Three different types of programme had therefore developed in an unplanned operational experiment: (1) in Tjirebon, backlog vaccination was followed by an intensive

BY COURTESY OF R. LINDNER

Plate 13.5. Reinhard R. Lindner (b. 1926) was the WHO smallpox adviser to the Indonesian programme from 1969 to 1971.

surveillance-containment programme; (2) in Bandung, a combined backlog vaccination and containment programme was directed by national supervisors; (3) in Bogor, a surveillance-containment programme only was conducted. The results of this experiment were to decide the subsequent strategy of the programme in Indonesia.

### Tjirebon Regency

The backlog vaccination operation had begun in July 1969 and ended 18 weeks later. During 2025 man-days, the teams visited 188 287 households in 267 villages. In all, 208 smallpox cases were discovered in 24 villages. On completion of the work, a sample survey showed that the proportion of unprotected children below 1 year of age had decreased dramatically, from 83% to 26%; of those aged 1-4 years, from 36% to 11%; and of those aged 5-14 years, from 3% to 2%. The illusion of a highly successful programme was shattered when just 2 days after the programme had been completed, 12 mobile teams from other provinces undertook a 2-day training exercise in Tjirebon. They discovered that in 7 infected villages transmission was still continuing. By tracing the sources of infection, an additional 118 cases and 3 undetected outbreaks were discovered.

Greater efforts were obviously needed, and a WHO consultant, Mr Michael O'Regan, was assigned in mid-November. On arrival, he found a frustrated but hard-working staff with a disorganized record system and no day-to-day operational programme. In the yaws and leprosy programmes in which Mr O'Regan had worked, methods had been developed for the systematic search for cases throughout extensive areas. Applying similar principles in Tjirebon, he obtained reliable maps and lists of villages from the army and, with regency staff, planned a programme consisting of a systematic village-by-village search for cases and house-to-house searches when outbreaks were found. The basic work was performed by 7 search teams each composed of 2 men on bicycles, their work being supervised by 2 search teams with vehicles. In every village, the programme was explained to the village leader and assurances were given that, should he report a case, a team would come to the village within 24 hours. Outbreaks, when discovered, were contained and the locality concerned was revisited weekly

until 4 weeks after the last case had occurred. Identification of the source of each outbreak permitted the discovery of other, unreported outbreaks. Each night the staff met, reported their findings and planned the following day's work. The initial search revealed that, as at 1 December 1970, there were 31 villages with active cases, but within 2 months transmission had been interrupted (Fig. 13.6).

Fig. 13.6. Tjirebon Regency: number of reported cases of smallpox, by 4-week intervals, 1969-1970. The last interval in 1970 includes 6 importations and 11 delayed reports of inactive cases.

Cases continued to occur as a result of importations from other regencies but these were quickly contained. The Tjirebon programme was the first in the Intensified Programme in which teams undertook a systematic area-wide search for cases without simultaneously performing vaccinations. The technique was later to be widely applied throughout Indonesia and was to prove vital in interrupting transmission in the Indian subcontinent.

### Bandung Regency

In Bandung, the combined surveillance-containment and backlog-fighting operation under the supervision of national staff had begun early in November 1968 and ended 26 weeks later. The teams visited 401 490 households in 242 villages and performed 163 194 primary vaccinations; 74 outbreaks with 565 cases were detected and contained. Altogether 4020 man-days were required. The resources needed to interrupt transmission were even greater than those expended in the Tjirebon programme.

### Bogor Regency

A single surveillance team with a vehicle had been assigned to Bogor in December 1969, after a national team investigating a reported outbreak discovered that not 1 but 18 out of 24 subdistricts were infected. Because no additional resources could be spared, the team continued to work alone. During 42 weeks, active search and containment detected 2101 cases in 101 villages, but transmission was completely interrupted; only 15 175 containment vaccinations were performed. Time was required to interrupt

Plate 13.6. Vaccinators in Indonesia moved from house to house, concentrating their efforts on young children and infants who had not been vaccinated previously. For this work, the bifurcated needle was especially valuable.

transmission in this densely populated area, but it was achieved at a cost of only 1802 man-days.

### Factors Affecting Transmission

In October 1970, after transmission had been interrupted in the 3 regencies, surveys were conducted to determine comparative levels of vaccinal immunity (Table 13.14).

Smallpox transmission had been rapidly interrupted in Tjirebon once surveillance-containment measures had been effectively applied, but vaccinal immunity was already

Table 13.14. Tjirebon, Bandung and Bogor Regencies: percentage of children unprotected by vaccination, by age group, October 1970<sup>a</sup>

Number of children examined	8 342	8 490	7 685	9 566

<sup>a</sup>Based on Koswara (in WHO/SE/71.30).

high there. Success had also been achieved in Bandung with improved supervision but at a considerable cost in resources. Bogor presented a contrast. There, transmission had also been successfully interrupted with surveillance-containment only, although 2-3 times as many unprotected children remained. The proportion that was unprotected was almost as high in the infected areas—in which containment vaccination had been extensive—as it was in the less endemic areas.

Everyone involved in the programme was surprised by the tenacity of smallpox in these and other regencies of Java despite comparatively high levels of vaccinia immunity and intensive surveillance-containment measures. It was a contrast to the situation in Brazil and western Africa, in which surveillance and containment had quickly stopped transmission, even in less well vaccinated populations (see Chapters 12 and 17). Indonesia, demographically and socially, was different in several respects (*Wkly epidem. rec.*, 1970a). Population density in Java was one of the highest in the world and, traditionally, families carried children who were sick from house to house to visit relatives. The tradition of isolating cases, so often observed in other countries, was uncommon. Thus, many more susceptible persons, on average, were exposed to smallpox cases than in most other areas. Because of high levels of vaccinia immunity and the greater frequency of exposure of susceptible persons, the age distribution of

Table 13.15. Comparative percentage distribution of smallpox cases, by age group, 1969<sup>a</sup>

Age group (years)	Jakarta	West Java	Brazil	Pakistan
0-4	58	56	36	29
5-14	37	33	37	39
≥ 15	5	11	28	31

<sup>a</sup>Based on Hartohusodo (in WHO/SE/71.30).

cases was different in Java from the corresponding distributions in Brazil and Pakistan, for example (Table 13.15).

In Java, more than half of all cases were found in children under 5 years of age; few cases occurred in adults. In Africa, South America and Asia, cases were more evenly distributed among all age groups.

Another factor of importance in smallpox transmission in Indonesia was climatic: smallpox was readily transmitted throughout the year (Fig. 13.7). Indonesia, located between 5°N and 5°S of the equator, did not have the wide seasonal fluctuations in transmission which were characteristic of countries such as Brazil, India and Pakistan (*Wkly epidem. rec.*, 1969a) (see Chapter 4). In these countries, in which transmission rates declined sharply during the summer and early autumn months, many chains of transmission terminated spontaneously and the containment of outbreaks during these periods was comparatively simple. In Indonesia no such circumstances obtained.

Fig. 13.7. Indonesia: number of reported cases of smallpox, by month, 1967-1972.

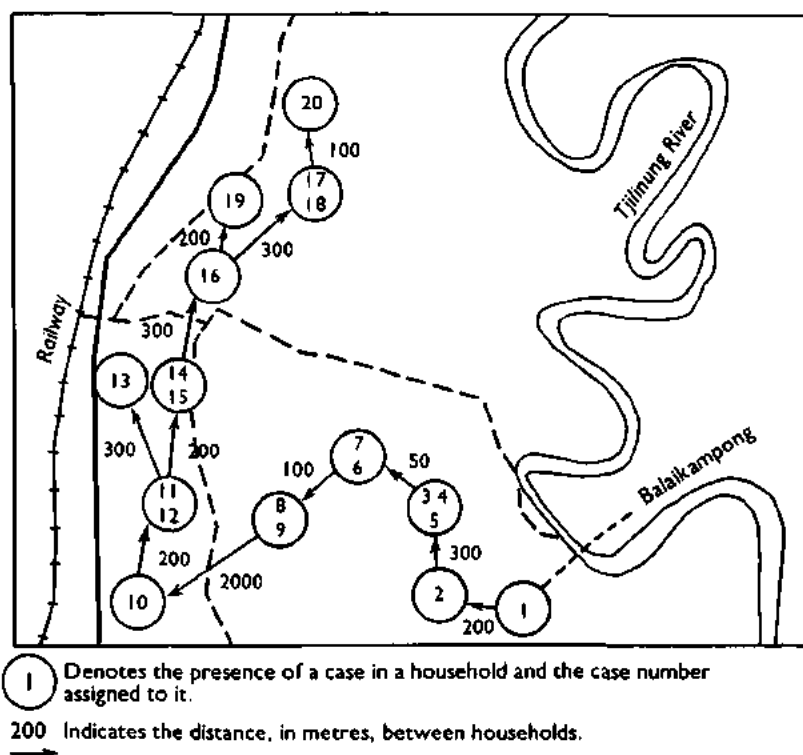

### Smallpox Transmission in a Well-Vaccinated Area

An outbreak in Passar Minggu (population, 14 376), a densely populated section of Jakarta City, vividly illustrated the ability of smallpox to continue to be transmitted even in well-vaccinated areas. In August 1970, the investigation of a death due to smallpox led to the discovery of a chain of infection involving 20 cases extending over a period of 21 weeks (see the figure below). A scar survey in the area revealed that only 2% of children between 5 and 14 years of age were unvaccinated (see table). Overall, the proportion of susceptible persons in the area was only about 6%, almost none of whom were adults.

*Passar Minggu: Vaccination Status of Children and Cases of Smallpox*  
(Emmet in WHO/SE/71.30)

Age group (years)	Percentage unvaccinated	Number of cases
<1	61%	2
1-4	20%	11
5-14	2%	5
≥15	—	2

The cases spread from one house to the next, usually over a distance of no more than 300 metres (see illustration). Nine of the cases resulted from intrafamilial transmission; the remainder occurred through the visits of susceptible children to infected households.

Similar occurrences of slowly spreading endemic smallpox in well-vaccinated populations were observed throughout the rural areas of West Java and, to some extent, of Central Java. In the other endemic areas of Indonesia, none of those which experienced smallpox after 1968 was so densely populated and smallpox there was far more easily contained.

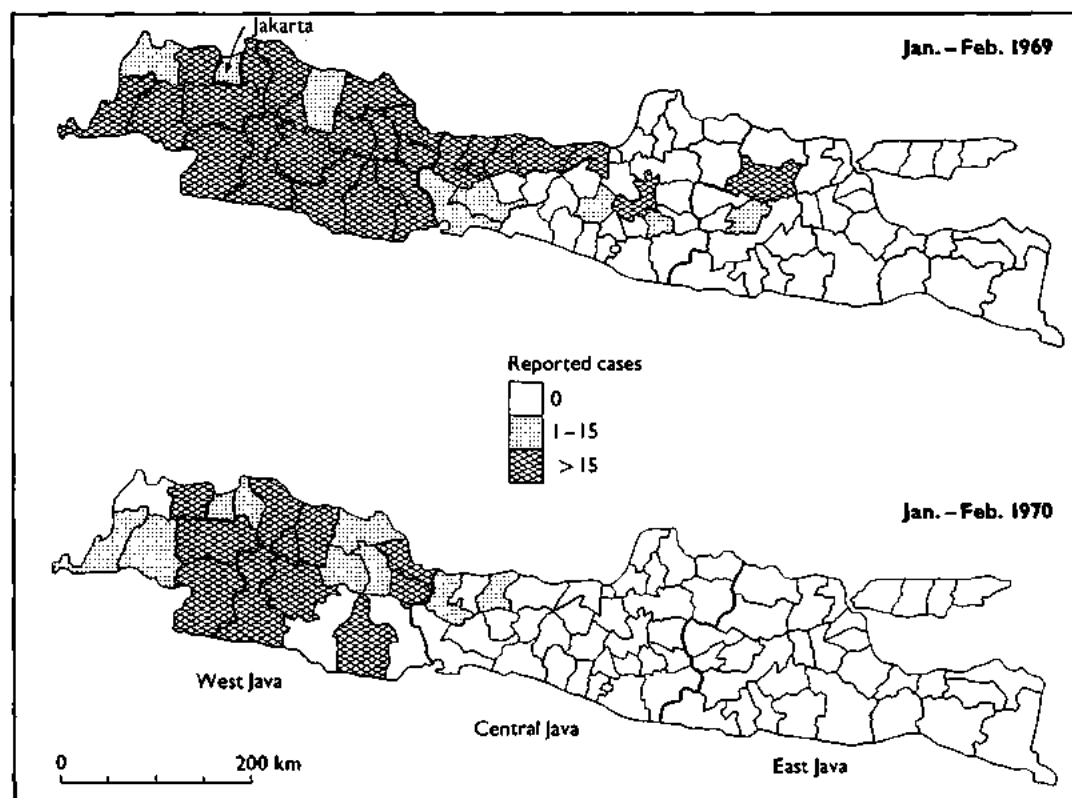

Fig. 13.8. Java: number of reported cases of smallpox, by regency, January - February 1969 and January - February 1970.

### THE SURVEILLANCE-CONTAINMENT STRATEGY BECOMES FULLY ESTABLISHED

Despite the problems of the backlog vaccination campaign and the diversion of resources from surveillance-containment activities, progress was made in the "east-to-west" strategy in Java (Fig. 13.8). By February 1970, endemic smallpox remained solely in West Java. In Central Java, during 1970, only 28 cases were detected, all of which represented outbreaks due to importations. Meanwhile, programme activities were extended to the outer islands.

Reporting, which had been so incomplete and greatly delayed, improved markedly in 1970 following the assignment of a full-time medical officer, Dr A. Karyadi, to assume responsibility for surveillance and data collection. Simplified standardized reporting forms were adopted for the weekly reports and a goal was set for the receipt of reports with a delay of no more than 2 weeks from provinces in Java and of no more than 3 weeks from the outer islands (Karyadi in WHO/SE/71.30).

Defaulting provinces were repeatedly contacted by letter, telegram, messenger and personal visits to promote compliance. Cooperation was sought from civil authorities as well. In the absence of an adequate postal service, many methods were utilized for the transmission of provincial reports, including couriers such as bus drivers, businessmen, special messengers and military personnel. Provincial authorities, with assistance from the smallpox eradication staff, sought to obtain promptly the weekly reports from regency medical officers and health units. To simplify reporting, the data requested were limited to the names of infected villages and subdistricts, the numbers of cases and deaths, the ages of cases, and the source of infection of each outbreak. Beginning in May 1970, a national weekly surveillance report was prepared which documented smallpox incidence and progress in the campaign. This was distributed to health authorities throughout Indonesia. In September 1970, Dr Karyadi was able to report that 95% of weekly reports were being received from provinces in Sumatra and Sulawesi within 3 weeks. Just one year pre-

viously, only about half as many reports were being received, and then with delays of up to 21 weeks. An increasing number of cases began to be reported from Sumatra, reflecting better notification (Table 13.16). Despite improved reporting, the number of provinces reporting cases began to fall drastically as from the beginning of December 1970 (Fig. 13.9).

In West Java, 8 mobile surveillance-containment teams worked with regency teams in carrying out active search operations and outbreak containment. As the year progressed, area vaccinators devoted less time to routine vaccination and more to systematic searches to detect cases and to contain outbreaks, as was done in Tjirebon. Initially,

### The Development and Use of the WHO Smallpox Recognition Card

Events which led to the development of the WHO smallpox recognition card and the use of schools in the search for cases in Indonesia occurred in Bandung. Among the many vaccinators engaged in search activities, there was one who recorded exceptional success in detecting outbreaks. Supervisors noted that, paradoxically, this vaccinator was considered to be one of the laziest workers—the last to leave for the field and the first to return home. When asked how he was so successful, he admitted that instead of visiting all the houses in a village, as instructed, he was visiting only the schools. There he showed children and teachers pictures of smallpox cases which appeared in a WHO teaching folder on smallpox diagnosis that had been prepared for Africa. Numerous case notifications were obtained with the minimum effort.

The teaching folder contained many different pictures of smallpox in African children. The photographs were small and the smallpox rash on a black skin appeared to differ somewhat from the rash on the skin of Indonesians, which was much lighter in colour. Nevertheless, most children had recognized the disease. Programme staff suggested the preparation of a single large picture of an Asian child with smallpox for use as a recognition card. Thus, the WHO smallpox recognition card was first prepared, encased in plastic for durability, and widely distributed around the world.

vaccinators were requested to search house by house, but because of the small numbers of vaccinators available, they were subsequently asked to contact specific persons and the staff of various facilities who would be the most knowledgeable regarding the existence of smallpox cases: (1) health units such as clinics, hospitals and aid posts; (2) civil officials, notably village chiefs, who in Indonesia had considerable authority in their designated areas; and (3) schoolchildren and teachers. Maps were prepared for each area, showing the principal sites and persons to be visited. A tour schedule was established to ensure that each was visited at least once a month. It was during these operations in West Java that the concept arose of printing smallpox recognition cards, depicting in colour a case of smallpox, which could be shown to those being contacted. This idea, which was proposed by Indonesian field staff to WHO regional office and Headquarters staff, was adopted and eventually tens of thousands of such cards were printed and distributed widely in Indonesia and other endemic countries throughout the world (see Chapter 10).

Containment activities were ever more rigorously defined and performed. In each outbreak, the "fire-fighting" or advance teams ensured that patients were isolated in their houses; the names of all villagers were recorded and everybody was vaccinated; the source of infection was identified and investi-

gated; and the teams remained in the village at least overnight to ensure more complete vaccination of those working in the fields or absent during the day at the market or in school.

### STRENGTHENING OF PROGRAMMES IN THE OUTER ISLANDS, 1970

Until 1970, resources and energies were principally directed to the containment of smallpox in the heavily populated island of Java. With the number of cases declining rapidly in Java during 1970 (from 1160 in January to 210 in June and to 49 in December) additional resources could be diverted to the two outer islands still harbouring smallpox—Sumatra and Sulawesi.

Sumatra had the higher priority because of the extensive inter-island boat traffic with Java. The programme in Sumatra had begun in July 1969 with an intensified vaccination campaign conducted by 567 vaccinators and 73 supervisors. As in Java, this had little effect on smallpox incidence. During 1970, more resources were made available to the programme (*Wkly epidem. rec.*, 1970d), notably transport and assistance from national campaign staff, and the strategy shifted from intensive vaccination to surveillance-containment. Smallpox spread less rapidly in the

more sparsely populated Sumatra and successful containment was easier, but this advantage was counterbalanced by a less-developed health structure and poorer supervision. In Sumatra, priority was given to the southern provinces, those nearest Java, to minimize the risk of importations. In October 1970, South Sumatra recorded its last cases, but the northern provinces (North Sumatra, Jambi and Riau) did not become smallpox-free until August 1971.

Sulawesi also began its programme in July 1969, with 355 area vaccinators and 38 supervisors. Endemic smallpox, however, was found only in South Sulawesi (population, 5 million). Progress was slow: the rugged mountainous terrain made travel difficult; communication with villagers was a problem because 15 different dialects were spoken there; and the civil and health infrastructure, after prolonged and devastating civil disturbances, was less developed than in Sumatra or Java. The interruption of transmission in Sulawesi was to require the best skills of experienced national and WHO staff and the most effective application of now well-

defined techniques for case search and outbreak containment.

Only 59 vaccination staff worked in South Sulawesi—less than half the number planned. Throughout 1970 comparatively little progress was made. However, early in 1971, with smallpox transmission all but interrupted in Java and with incidence rapidly diminishing throughout Sumatra, senior national staff and WHO advisers transferred to Sulawesi, and additional automobiles, motor cycles and bicycles were assigned to the programme. The WHO smallpox recognition card began to be used in contacts with schools and civil authorities. In March 1971, a planned programme of meetings with village chiefs and other civil administrators was instituted in order to acquaint them fully with the programme and to solicit their help in the prompt reporting of suspected cases. Many conscientiously fulfilled this responsibility through special search programmes which they independently organized. Isolation of patients in their houses, containment vaccination, both by day and by night, search for the sources of outbreaks and identification of

<sup>a</sup>No cases were reported in Kalimantan, Bali, Nusa Tenggara, West Irian or Jogjakarta during this period.

exposed individuals who had left infected villages were more rigorously executed. With improved surveillance and containment measures and heroic efforts by national and WHO staff, smallpox transmission came to an end in South Sulawesi in November 1971 (Table 13.17).

Immediately after the apparent detection of the last case, the 1208 vaccinators in Sulawesi, Sumatra and Kalimantan searched village by village during a 4-month period, reaching 18 205 (73.5%) of the 24 781 villages in the process. Although 920 suspected cases were examined and 76 specimens were taken, none revealed the presence of smallpox (WHO/SE/74.63, Cuboni et al.).

In the island of Kalimantan (population, 5 million) and in the other provinces of Sulawesi, provincial and local health staff, without significant additional support from national or WHO staff, had unexpectedly succeeded in interrupting transmission as early as November 1969. How this was achieved is not fully documented. Kalimantan had experienced a major epidemic of smallpox, with large numbers of reported cases, during 1965-1967. The epidemic may have begun before 1965, although no earlier data are available. Because reporting was so incomplete, it is probable that the actual number of cases may have been 100 times or so greater than the number recorded.

Programme staff at the time speculated that natural immunity induced by the epidemic, combined with extensive vaccination,

had so reduced the number of susceptible persons that transmission was interrupted even though the surveillance-containment programme was much less effective than in other areas. However, a high level of immunity was not the primary explanation for the interruption of transmission in Kalimantan and in Central, South-east and North Sulawesi, as was shown in a February 1974 survey. At that time, Indonesian staff conducted random cluster sample surveys among children throughout these provinces (Table 13.18) (WHO/SE/74.66, Cuboni et al.). In most provinces, more than one-third of all children remained susceptible. Immunity levels were substantially below those in most of Java, in which health services were far more extensive.

Important to the interruption of transmission was the fact that the populations of Kalimantan and Sulawesi were concentrated in discrete areas, primarily along the coast. Communication between these population centres was much more difficult than in Java or Sumatra. In effect, they were more like a series of comparatively small island populations than a land mass over which travel was easily accomplished. Many outbreaks undoubtedly terminated spontaneously and others responded to comparatively perfunctory containment and vaccination activities, as was the case in much of Africa, for example. After transmission had been interrupted in an area, smallpox was reintroduced only infrequently.

## INDONESIA'S LAST OUTBREAK, 1971

After the last cases occurred in Sulawesi in November 1971, 4 weeks elapsed during which no smallpox cases were reported in Indonesia. It appeared that transmission had been interrupted, but on 14 December 1971, the Director of the Smallpox Eradication Programme received a report from Tangerang Regency (one of the 24 regencies/municipalities in West Java) of 45 cases and 6 deaths in Sepatan Subdistrict, only 28 kilometres from Jakarta. Tangerang (population, 1 million) had recorded its last cases in February 1971, fully 10 months earlier. A village-by-village search had been conducted in West Java between June and August 1971 in the subdistricts which had reported cases during 1970-1971; lack of personnel had precluded a search in all subdistricts. Sepatan Subdistrict had not reported cases during this period and thus had not been searched.

On investigation, it was found that as early as December 1970, a whole year earlier, many cases in Sepatan had begun to be reported to the health centre by the subdistrict's vaccinator. The medical officer of the health centre periodically organized ineffectual mass vaccination campaigns to control the outbreaks but deliberately suppressed the reports of smallpox, fearing that he might be

punished for incompetence. In mid-December 1971, a provincial mobile surveillance and supervisory team visited the area on routine tour and was informed of the outbreaks by the local staff (Cuboni et al. in WHO/SE/76.85).

Search and containment activities were immediately instituted. In the realization that the suppression of reports might be widely prevalent, the decision was made to offer a transistor radio to any person who reported an active case of smallpox. This, so far as is known, was the first occasion in the Intensified Programme when a reward was offered for case reporting. It proved to be highly effective. Numerous suspected cases with illnesses of all types were reported by people throughout the area. Eventually, 160 smallpox cases with 15 deaths were confirmed in 3 villages (total population, 7982) of Sepatan Subdistrict; nearly one-third were unprotected when containment vaccination had begun (Table 13.19).

The outbreak had started in Sarakan village in December 1970 (Fig. 13.10), 1 year previously, as a result of an importation from West Jakarta. Smallpox spread slowly, only 14 cases occurring between December 1970 and May 1971. Eventually, the outbreak was contained by a local vaccinator. Meanwhile the disease had spread to Sangiang village in May 1971 and, in September, numerous cases began

Table 13.19. Sangiang, Sarakan and Gaga villages, Sepatan Subdistrict: number of vaccinations performed during containment operations, 1972

to occur. In all, 131 persons eventually developed smallpox in this village of 3106 persons. At the end of November the disease was reintroduced into Sarakan village and, in December, it spread to nearby Gaga village. Finally, late in December, an outbreak of cases developed in a village 80 kilometres distant. The last 2 known cases in Indonesia occurred on 23 January 1972, one of them in Gaga village, and the other in Kupahandap village.

Concerned that other hidden foci might be present elsewhere in Indonesia, the programme staff decided in May 1972 to offer a reward of 5000 rupiah (US\$12) to anyone reporting a case. This was widely publicized. The following month, teams from throughout Indonesia began an active search programme. Numerous rumours were investigated and many specimens were examined, but no further cases were found. A summary of the numbers of specimens examined in laboratories during 1969–1973 (Table 13.20) indicates the extent of this activity.

### MORBIDITY AND MORTALITY PATTERNS

Smallpox in Indonesia exhibited two unusual features: (1) an exceptionally large proportion of cases among younger children; and (2) case-fatality rates which were often lower than those observed elsewhere in Asia.

In June 1969 the Joint WHO–Indonesia Assessment Team analysed the age distribution of 3823 cases in selected areas and during periods when reporting was considered to be reasonably complete (Table 13.21). The age distributions were similar in West and Central Java and Jakarta, in which smallpox

was then endemic. Cases in East Java occurred primarily in outbreaks following importations and the patients were generally older, as was the case in other non-endemic areas. Excluding the data for East Java, 68% of cases occurred in children aged 0–4 years, a group which comprised only 18% of the population of the country. A surprisingly high incidence—about 12%—was found in infants under 1 year of age, twice the proportion recorded in India.

Smallpox spread in Indonesia more readily than in most parts of the world and transmission occurred throughout the year with no apparent seasonal pattern. The facility of spread can be attributed to the high population density and the custom in Indonesia of carrying sick children to visit relatives, thus exposing many more susceptible individuals.

The reported case-fatality rates in many years and during most outbreaks appeared to be lower than those in the Indian subcontinent. This is the converse of what might have been expected, because cases in Indonesia were proportionately more numerous in the very young, among whom case-fatality rates are customarily higher. The question whether case-fatality rates in Indonesia were substantially and uniformly lower than those in the Indian subcontinent was never resolved. The reporting of both cases and deaths was grossly incomplete throughout Indonesia before 1968. The degree of underreporting of cases compared to that of deaths undoubtedly differed from year to year. This probably accounted for such discrepancies as a case-fatality rate of 10% in 1950 and one of 44% only a year later. With the commencement of the national programme, the reporting of cases gradually improved, more rapid pro-

Table 13.20. Indonesia: laboratory examination of specimens, 1969-1973

Year	Number of regencies submitting specimens	Number of specimens	Number positive for variola virus	Number positive for vaccinia virus
1969	19	235	74	0
1970	37	250	55	0
1971	38	150	15	0
1972	113	1 009	12	1
1973	109	599	0	6

gress being achieved in some areas than in others. However, as in other countries, few efforts were made to improve the completeness of the notification of deaths. Since the programme's goal was to interrupt the transmission of smallpox, it was more important to know where and how many cases were occurring than to be aware of how many deaths had taken place.

In containing outbreaks, especially in 1970-1971, the smallpox eradication staff carefully enumerated cases, and because teams remained in the infected areas, the numbers of deaths (which usually occurred 1-2 weeks after the onset of illness) were also known fairly accurately. In those outbreaks, case-fatality rates of 5-10% were often observed, about half as high as the rates in the Indian subcontinent. Data from Jakarta, however (Fig. 13.11), consistently showed much higher case-fatality rates. Jakarta had had a reasonably complete system for the notification of deaths since 1965 and for the reporting of cases since 1968. The case-fatality rates were twice as high as those of West Java, a province which surrounds it and across whose borders residents moved freely. In other respects, the populations were essentially similar with regard to nutrition and general health. If it is assumed that the virus strain in Jakarta was the same as that in West Java, the obvious explanation for the lower rates in West Java would be incomplete notification of deaths. And yet the case-fatality rates in

West Java were similar to those observed later in some well-studied outbreaks elsewhere in Indonesia. The observations were never reconciled.

## CONCLUSIONS

Smallpox transmission in Indonesia was interrupted just 3 years and 7 months after the programme began in July 1968. This was a remarkable achievement considering the country's size, population and the limited international resources provided. The experience in Indonesia had a profound effect on other programmes during the succeeding years. Among the innovations were the WHO smallpox recognition card, the offer of a reward for reporting a case, a procedure for the systematic search for cases throughout a wide area, and the demonstration of the efficacy of a search based on contact with teachers and schoolchildren. More important, the success of the surveillance-containment strategy was forcefully communicated by Indonesian programme staff to their counterparts in the Indian subcontinent through papers and seminars. Of particular significance was a specially convened WHO inter-regional seminar in New Delhi in December 1970. One of the papers, contributed by Dr Koswara, the Indonesian programme's director (Koswara in WHO/SE/71.30), was

entitled: "Is Routine Vaccination a Necessity in a Smallpox Eradication Programme?" The author concluded that proper surveillance–containment action had brought smallpox under control in a short period, while routine vaccination and mass vaccination campaigns had had little effect in interrupting transmission. Many participants at the conference severely criticized this view, which they considered tantamount to heresy. At that time, Indonesia had not yet stopped transmission in Java, let alone in Sumatra or Sulawesi. Because of this, few of the participants were persuaded by Dr Koswara's arguments. However, with the occurrence of Indonesia's last case in January 1972, it was apparent that the 11-year-old programmes in India and Pakistan had much to learn from the Indonesian experience. A strong stimulus for change was provided.

### INTRODUCTION

In 1967, endemic smallpox in continental southern Asia extended over a contiguous block of countries from Afghanistan through West Pakistan, India, Nepal, Bhutan, and East Pakistan. Epidemiologically, this area could be subdivided into two parts: a western part consisting of Afghanistan and West Pakistan and an eastern part that included India, Bhutan, Nepal and East Pakistan. Separating these two parts was the heavily guarded border between India and West Pakistan. Few persons travelled across this border and, so far as is known, no cases of smallpox were imported across it after 1966. The health programme of West Pakistan functioned quite independently of that of East Pakistan, and in December 1971, when

the latter province became the independent state of Bangladesh the two programmes were, of course, entirely separate. The programme in East Pakistan/Bangladesh is described in Chapter 16 and the programmes in India, Bhutan and Nepal in Chapter 15.

West Pakistan and Afghanistan were epidemiologically closely linked because numerous travellers moved freely across their long common border (Fig. 14.1), including several hundred thousand nomads who lived in Pakistan in the winter and in Afghanistan in the summer. Smallpox spread easily across this border.

Pakistan and Afghanistan are both Muslim countries but differ greatly in most other respects—politically and geographically, in historical and socio-economic development and in the manner in which their smallpox

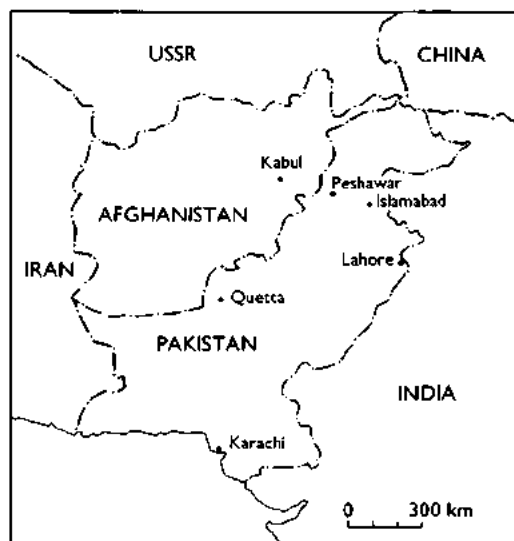

Fig. 14.1. Afghanistan and Pakistan and adjacent countries.

eradication programmes evolved. A WHO-assisted vaccination campaign had begun in 1963 in Afghanistan. By 1967, encouraging reports from programme staff made it seem reasonable to expect that systematic vaccination in the towns and cities and a national outbreak-containment programme would rapidly interrupt transmission. This optimistic view faded a year later, when it was discovered that itinerant hereditary variolators were active throughout much of the country, particularly in the extensive remote mountainous areas, spreading smallpox as they travelled. Because Afghanistan was a country with few roads, a primitive health infrastructure and orthodox religious practices which impeded vaccination, it was feared that transmission might be sustained in isolated, virtually inaccessible areas despite the best efforts at control. As late as 1971, WHO senior staff believed that Afghanistan might be the endemic country most likely to thwart the ultimate goal of global eradication. An extraordinary programme and a heroic effort by Afghan and WHO staff were to produce yet another surprise when, in September 1972, Afghanistan succeeded in interrupting smallpox transmission.

Pakistan, in contrast to Afghanistan, had a comparatively well developed health infrastructure, extending throughout most of the country, and a population which generally could be easily reached by the relatively extensive network of roads. A programme of

routine smallpox vaccination had been established since the late 19th century; variolation was rarely practised. The epidemiological behaviour of smallpox in Pakistan had been characterized during 1966–1967 in a unique series of studies whose findings were to prove significant in shaping the strategy of eradication programmes in other countries. An important observation was that urban centres played a crucial role in sustaining smallpox transmission, especially during the summer and autumn, when the incidence was low. The investigators discovered, however, that even during the months of highest incidence and in what was considered to be a heavily infected district, the number of outbreaks was sufficiently small to require only a few teams to detect and contain them. Because they found the levels of vaccinal immunity to be already high in Pakistan, the investigators recommended that priority should be given to detecting and containing outbreaks, especially in urban areas and during the season of lowest incidence. Paradoxically, however, Pakistan was among the last countries to adopt a strategy based on these recommendations. Until 1973, national and WHO programme staff persisted in executing a mass vaccination campaign which was indifferently supported and not satisfactorily conducted. Despite the many factors favouring smallpox eradication, transmission was not interrupted in Pakistan until October 1974.

Meanwhile, there was little communication and virtually no coordination of activities between the programmes in the two countries. Numerous cases of smallpox were imported into Afghanistan from Pakistan and special surveillance programmes had to be developed to combat the threat they represented, which became all the more serious when Afghanistan succeeded in interrupting transmission more than 2 years earlier than Pakistan. The two programmes differed greatly and are discussed separately in this chapter.

## AFGHANISTAN

Few of the endemic countries posed as many difficult and unusual challenges as did Afghanistan. In 1967, this isolated, landlocked country was in an early stage of economic and institutional development. The government structure was rudimentary, and in some remote areas the central authority was

not recognized. The population—90% of which was illiterate—is estimated to have been 11.9 million in 1968 (United Nations, 1985), although no census had ever been taken.

The Hindu Kush mountain range, with peaks as high as 7500 metres, extends from the extreme north-east border with China towards the south-west, much of central Afghanistan having an altitude of more than 2000 metres (Fig. 14.2). Because of snow, this area was largely inaccessible for almost half the year. The south-western part of the country is mainly desert, where the extreme heat precluded most programme activities during summer. Except for a single paved all-weather road that circled the country, with occasional branches to provincial capitals, the roads were extremely poor, challenging even heavy-duty vehicles. There were no navigable rivers, no railway, and only limited air connections. Programme operations and efforts to communicate with the population were hampered by illiteracy and by the use of 3 different major languages—Dari, Pushtu and Uzbeki.

Most of the population lived in the 20 000 villages in rural areas and less than 15% in the main cities of Kabul, Kandahar, Herat and Mazar-i-Sharif. Religious practices were strict among the predominantly orthodox Sunni Muslim rural dwellers, and religious leaders were highly influential. Of importance to smallpox eradication was the observance of *purdah*, whereby women were secluded within their homes and the male heads of house-

hold refused to permit them to leave the house for vaccination or to be vaccinated by male vaccinators.

The health structure was rudimentary. In 1965, there were reported to be 19 primary health centres and 60 hospital-clinics staffed by physicians who were responsible for both curative and preventive services, although few offered even the most elementary preventive measures (World Health Organization, 1965b).

### Smallpox Control before 1963

For centuries, variolation had been practised throughout Afghanistan by traditional variolators, the technique usually being communicated from father to son. Many variolators travelled considerable distances in the course of their work. A fee of 10–15 afghanis (US\$0.15–0.20) was the usual charge. Scabs (rarely pustular material) from a patient were collected and ground with a mortar and pestle, and the powder suspended in a liquid. The suspension was inoculated by scratch or by pinprick on the forearm or near the wrist. Variolators usually obtained fresh material each year, and therefore variolation tended to be performed during the autumn and winter months, after the number of cases had begun to increase.

Vaccination was all but unknown in Afghanistan until 1936, when a campaign was organized that succeeded in vaccinating 3 million persons over a 3-year period; liquid vaccine produced at a laboratory in Kabul was used (Berke, 1956). This laboratory continued to produce small amounts of vaccine which, during subsequent years, was primarily used in and around Kabul. Because the vaccine was of questionable potency, as well as being thermolabile, vaccinal immunity in 1967 was probably not high, even in Kabul.

In 1949, Afghanistan began to keep records of the number of cases of smallpox. Between 1949 and 1968, the annual total ranged from a low of 66 cases in 1966 to a high of 2179 cases in 1952. However, the figures had little meaning since the only cases reported were those which were diagnosed in the country's few health centres. A simple calculation provides an approximation of the probable extent of underreporting. In a population of 10 million, each year about 300 000 would survive the perinatal period to constitute a new group of susceptible subjects. Because

JOHNS HOPKINS UNIVERSITY

JOHNS HOPKINS UNIVERSITY

**Plate 14.1.** For hundreds of years, variolation had been widely practised throughout Afghanistan by hereditary variolators using kits such as these. Scabs were collected from a recovering patient and kept in a container such as a metal box (**A**) or horn (**B**). Before inoculation, the dried scabs were ground up, usually in a primitive mortar and pestle (**B**). A liquid such as honey or water with spices was added and a drop of the suspension was applied to the skin. This was then inoculated into the superficial layers of the skin, using a needle or lancet. Sometimes a special strip of cloth (**B**) was used, and reused repeatedly, to bind the site of the incision until a pustule formed.

few individuals were successfully vaccinated, almost all would eventually become infected with smallpox. Thus, on average, 300 000 persons would experience smallpox each year, either by natural infection or as a result of varioration—i.e., more than 350 times the average of 840 cases reported annually between 1949 and 1963.

### Commencement of a WHO-assisted Vaccination Campaign, 1963

Following the Twelfth World Health Assembly's resolution in 1959 to embark on the global eradication of smallpox, Afghanistan sought and obtained assistance from WHO to begin a special campaign. It was one of only a few countries to receive technical and material support from WHO for field activities in smallpox eradication during the period 1959–1966. A WHO adviser was assigned to Kabul in 1962; in March 1963, a vaccination campaign began in the capital. During the following year, the campaign was extended to 9 provinces (World Health Organization, 1965b). Freeze-dried vaccine provided by the USSR and locally produced liquid vaccine were used. By the end of June 1964, 392 026 of the 400 000 residents of Kabul were reported to have been vaccinated by a staff of 139 male vaccinators and 7 female vaccinators and auxiliary midwives. Twenty-five of the vaccinators were then kept in Kabul "to carry on the maintenance phase and to fight epidemics", as the WHO adviser reported. The remainder were assigned to the provinces to work under the direction of provincial medical officers. Although large numbers of people were subsequently reported to have been vaccinated, the reports were thought to be greatly exaggerated.

In 1965, 3 additional groups, each composed of 70 vaccinators, were trained and dispatched to Kandahar, Ghazni, Wardak and Bamian Provinces (see Fig. 14.3). Young physicians, conscripted for government service, were assigned to supervise each group but few were willing to leave Kabul. What was achieved is unknown because no records were kept.

During the following 3 years, additional resources were provided by WHO, but little progress was made. At the end of 1968, the uncoordinated and poorly supervised series of activities could scarcely be characterized as a programme. The physician in charge of small-

pox eradication was also responsible for all the country's communicable disease control activities and could therefore devote little time to the smallpox eradication programme. Young medical graduates, carrying out their compulsory service, continued to be assigned to provide direction but few spent more than a month or two in the field before arranging to be transferred. In the staff hierarchy there were only a few sanitarians between the programme director and the vaccinators, and the turnover among them was almost equal to that of the physicians. The problems were further compounded by inadequate government funds and a complicated financial system which typically resulted in delays of 3 months or more in the payment of salaries and, frequently, a lack of funds to purchase petrol. Within the government structure, the execution of even simple tasks was time-consuming. For any purchase, for instance, 3 responsible individuals were required to visit the bazaar to bargain, to obtain a receipt for the purchase, and then to report to an administrative section where the transaction could be recorded.

The support provided by WHO contributed little. The WHO smallpox adviser devoted most of his time to the preparation of letters advising his Afghan counterpart as to what should be done and to the compilation of monthly reports. He rarely travelled out of Kabul. Two WHO nurses, assigned to the programme in 1967, likewise travelled little and, although sharing an office with the adviser, received most communications from him in the form of typed memoranda. Eighteen vehicles had been provided to the programme of which 9 were not sufficiently roadworthy to leave Kabul and 7 had been coopted for the use of various officials in the Ministry of Health.

In April 1968, a medical officer responsible for smallpox eradication in the WHO Regional Office for South-East Asia reported in despair that no one knew where the provincial vaccinators were stationed or what they were doing. No records were kept, in part because most of the vaccinators were illiterate. The group of vaccinators in Kabul was periodically dispatched to the field when a report of an outbreak was received. They travelled in a large flatbed truck to the site with orders to vaccinate everyone in the area. After some days or weeks had elapsed, they gradually filtered back to Kabul. No report was prepared on what had been accomplished.

Meanwhile, the USA had been approached by the Afghan government and asked to send female volunteers to assist in vaccinating women throughout Afghanistan. Women, it was said, could not be vaccinated by male vaccinators nor could they leave their dwellings in most areas. The volunteers would be expected to work with Afghan women counterparts as members of teams vaccinating from house to house. The concept was attractive but unrealistic. A small contingent of United States volunteers could themselves vaccinate no more than a fraction of the population, and given the religious strictures of the country, the recruitment of Afghan women was all but impossible.

The unsatisfactory vaccine then being used presented no less of a problem. Although liquid vaccine production had ceased in Kabul, the freeze-dried vaccine provided through bilateral assistance did not meet accepted standards, as was attested by protocols provided by the production laboratory itself. Moreover, all vaccine was then being stored at room temperature, which caused it to deteriorate even further.

Finally, the scope of the smallpox problem itself was not comprehended. Early in 1967, the WHO adviser, noting that only 72 cases had been reported in 1965 and 66 cases in 1966, confidently estimated that in the entire country there probably were not more than 300 cases each year, most of them in children. If indeed there were so few cases, it could be inferred that there were comparatively few chains of transmission. Geneva staff, who were ignorant at that time of the moribund state of the programme, hopefully proposed an alternative strategy to country-wide vaccination: (1) intensive containment of known outbreaks by special teams; and (2) a programme of primary vaccination of children in the cities and towns. This, it was felt, might serve to concentrate resources in priority areas and alleviate the problem of supervising vaccinators so widely dispersed over the countryside. No action was taken, however.

When Henderson and Dr Jacobus Keja, of the WHO intercountry team advising on smallpox eradication, visited Afghanistan in October 1968, the full array of problems became apparent. Not only did they discover that the programme existed in name only, but they found that conditions in Afghanistan differed substantially from the situation described in reports and were far more serious than had hitherto been thought. Even with

the woefully inadequate notification system, 334 cases were recorded in 1967 and 739 in 1968. Smallpox was far more widespread than had been supposed. Variolation was found to be common and some, perhaps many, of the outbreaks resulted from this practice. The fact that variolators were most active in the least accessible parts of the country was of particular concern. They retained infected scabs for 1-2 years and travelled considerable distances to perform inoculations. Moreover, because the government had begun to discourage the practice, villagers usually refused to identify the variolators, fearing that they would be punished. On the basis of these observations, it was suspected that smallpox transmission, perpetuated by variolation, might persist indefinitely among a remote, comparatively small population of susceptible persons. The optimistic outlook in 1967 that Afghanistan might soon interrupt transmission gave way towards the end of 1968 to fear that the country might prove to be the world's last and possibly permanent reservoir of smallpox.

The previously suggested strategy of vaccinating the more accessible members of the population, coupled with the search for cases and the containment of outbreaks, could not solve the problem caused by variolation. Special efforts would be needed to educate villagers about the hazards of variolation and to identify variolators and persuade them to stop their practice. It was recognized, however, that such efforts would be only partially successful because the identity of variolators was kept secret. Other measures were required. The only possible approach, apart from outbreak containment, appeared to be that of vaccination of the population at large to diminish the number of susceptible individuals available to variolators as clients and as a source of scabs. This would be particularly important in the remote areas in which variolation was most prevalent. Meanwhile, special efforts would be required to characterize epidemiologically all outbreaks so as to uncover evidence of variolation. Considering the poor record of achievement of the programme during the 6 years 1963-1968 the task appeared formidable, perhaps impossible.

#### **Changes in the Strategy and Structure of the Eradication Programme, January 1969**

During extended discussions between government officials and Henderson and Dr

Keja, a new plan of operations was formulated. The key Afghan officials who provided the essential impetus in the design and implementation of the programme were the perceptive and energetic Dr Sayed M. Saidi, President of Preventive Medicine, and Dr A. Omar, Deputy Minister of Health. An agreement was signed by the government on 12 December 1968 and by WHO 3 weeks later. The plan called for the appointment of a full-time Afghan medical director who was to be given sufficient authority and responsibility to direct the programme and the establishment of 4 operational zones (Fig. 14.3)—Kabul, Kandahar, Kunduz and Herat—with a zone office in each. A full-time medical officer and 3 sanitarians, assisted by a WHO adviser, would be assigned to each office. Each zone director was to be delegated full responsibility for the programme in his zone, with authority to discipline personnel and to recruit and train replacements, to requisition fuel for transport and pay for repair and maintenance, and to make all necessary travel

arrangements for staff within the zone. Although the recommendations were administratively sound, such responsibilities had not previously been assigned to supervisory staff outside Kabul. Despite a conscientious effort to achieve the requisite delegation of authority, the lack of decentralized authority plagued the programme throughout its existence.

Personnel needs were identified and a budget was drawn up (Table 14.1). With only 4 motor vehicles and 6 motorcycles then available, it was recognized that the programme could not become fully operational until at least August 1969, when the delivery of an additional 44 vehicles, provided by WHO, was expected. Each province was allotted 1 vehicle each for the zone director, the WHO adviser, an outbreak-containment team and an assessment team, and 5 vehicles for the vaccination teams. Other vehicles were to be kept in reserve.

The plan called for vaccination teams to move systematically from village to village

<b>Total</b>		<b>201 000</b>
<b>Grand total</b>		<b>4 429 980</b>

<sup>a</sup> For the Afghan year 1348 (21 March 1969–20 March 1970).<sup>b</sup> 10 afghanis were worth approximately US\$0.15. The total national budget was thus equivalent to about US\$66 500.

and from house to house, preceded 3–10 days earlier by a visit of the team's leader to inform village leaders of the programme and to instruct them about the hazards of variolation. Instead of the name of each vaccinated person being recorded, vaccinations would be tabulated by age group on a tally sheet. An assessment team would visit a sample of children in the villages 1–3 weeks later to assess vaccination status, take rates following vaccination and the prevalence of variolation scars. Surveillance–containment teams would visit civil and health authorities in their respective zones to seek cooperation in reporting and to investigate and contain outbreaks.

In addition to miscellaneous supplies such as refrigerators and office equipment, WHO agreed to provide up to 4 million afghanis (about US\$60 000) each year for travel allowances for headquarters and zone staff and for petrol and vehicle maintenance and repairs. Eventually WHO provided Afghanistan with more than US\$1.4 million in support of the programme (Table 14.2), an amount equivalent to about US\$0.12 per head of population. In addition, freeze-dried vaccine was provided by the USSR and from contributions received by WHO.

In February 1969, Dr A. G. Rangaraj, a newly recruited senior WHO adviser on smallpox eradication, joined the programme, replacing the previous incumbent. Dr Rangaraj had served with distinction in the Indian Army Medical Service and brought to the programme a unique expertise and capabi-

lity in programme organization and logistics. With the 2 WHO nurses already assigned, Miss Khin Mu Aye and Miss Ludmila Chicherukina, and later an additional epidemiologist, Dr V. V. Fedorov, an exceptionally effective WHO advisory team was created. In May 1969, the Afghan government appointed a no less determined and energetic full-time programme director, Dr Abdul Mohammad Darmanger, who ably fulfilled this role for the next 5 years.

#### *Establishment of zone offices and effective field activities*

Most of the Afghan smallpox eradication programme staff lived in Kabul, and the attractions of urban life discouraged prolonged work in the field. It was felt that a second base of operations, outside Kabul, with staff recruited from the local area, would facilitate field work. An office-cum-dormitory was rented in Kandahar and some work began from this base as early as November 1968. The staff initially consisted of an Afghan medical officer as director, 6 sanitarians, 44 vaccinators, 3 drivers, a cleaner, several volunteers from the USA and the 2 WHO nurses. Work was frequently interrupted, however, because of numerous national and religious holidays and periodic strikes by Afghan staff when they failed to receive salary or travel allowances because of the complicated payment system. Another hindrance was the frequent change of zone medical

**Plate 14.2.** A: Sayed M. Saidi (1923–1970), President of Preventive Medicine in the Ministry of Health of Afghanistan, provided a new impetus to the programme in 1968. B: Arcot G. Rangaraj (b. 1917) became the senior WHO adviser on smallpox eradication in Afghanistan in 1969 and, with Abdul Mohammad Darmanger, his Afghani counterpart, directed Afghanistan's first, and highly effective, nation-wide health programme. He later served with the smallpox eradication programmes in Bangladesh and in the Arabian peninsula.

directors (3 in the first 8 months alone), few of whom were anxious to undertake field work, or to live outside Kabul. Nevertheless, by June 1969, almost the whole population (742 000) of Kandahar, the largest province in the zone, had been vaccinated. Assessment showed that more than 90% of the population had been protected.

It became apparent during this period that, contrary to previous ideas, the 30 United States women volunteers were not essential to the work of vaccination. It was found that when village leaders were properly informed about the nature of the programme, women were usually permitted to be vaccinated by male vaccinators, although sometimes on the forearm or wrist rather than on the upper arm, the customary site of vaccination. From the investigation of outbreaks, it also became apparent that few cases occurred among women, most of whom by the age of puberty had experienced smallpox or had been variolated or vaccinated. Thus, even if some were missed during the vaccination campaign, only a small proportion would remain susceptible. Accordingly, the volunteers were reassigned to assessment and surveillance teams and some helped to establish the necessary administrative and support structure at headquarters and zone offices. They were a dedicated group and made important contributions to establishing the new programme, but when

any of them left they were not replaced. Their number had dwindled to 9 by 1970 and to only 1 by 1971.

In July 1969, a third office was established in Baghlan Province, for Kunduz zone, with 2 team leaders, 2 sanitarians and 17 vaccinators. One of the WHO nurses was transferred to Baghlan and several United States volunteers were deputed to work in this office.

Not unexpectedly, a reorganization and reorientation of activities of the magnitude proposed in the plan of operations caused serious difficulties. A joint Afghan–WHO assessment team made an inspection visit in August 1969 and detailed in their report continuing major problems:

- The national programme office had no telephone, secretarial assistance, stationery, files, forms or records. Sanitarians appointed (as administrators) had neither the background nor the skills necessary to discharge their duties.
- The director had no apparent authority—i.e., he had no direct access to a defined budget, no authority either to establish or to enforce personnel policies and no authority to deploy assigned resources (e.g., vehicles, subsistence allowance) without individual written authorization by his immediate superior. Indeed, his superiors appeared to act independently with smallpox eradication programme resources without prior consultation.

● Only 1 team in 5 in Kandahar zone had worked at all from mid-June to early August and then for only 1 week. In August, 13 of the 53 team members in Kandahar had been sent for military service. Field allowances were not being paid nor were funds available for petrol. These factors were responsible for a strike by vaccinators in Kunduz zone.

● The director's lack of authority was illustrated by his inability to dispatch a truck to the airport to pick up a vaccine shipment; this resulted in the vaccine remaining in a hot unventilated shed for 8 days.

● The director had been unable to obtain maps for field operations although the Malaria Institute could do so and tourists could buy them from the Cartographic Institute.

● All teams in Kabul zone had been assigned throughout the summer by Ministry officials to perform cholera vaccination.

● No provincial vaccinators were working with the teams, contrary to prior agreements.

● In Kabul zone, there was no zonal administrative structure and no defined plan of action.

● Vehicles had been out of operation for extended periods and reassigned to other programmes; 2 of 7 large vehicles provided by WHO could not be located, nor could one-third of the motor cycles provided.

The assessment team travelled widely throughout Afghanistan in August 1969, talking with health staff and others and

conducting surveys for evidence of pockmarks and vaccination scars. There were encouraging findings. Everyone with whom they spoke reported that variolation had markedly diminished in recent years, and of 4999 persons examined in their survey, only 3 were found who had been variolated within the preceding 3 years. The reporting of cases was known to be incomplete but, despite intensive search, the team could find no cases not already known to the programme staff. In areas in which the systematic vaccination campaign had been completed, only 7% of the population remained unprotected (Table 14.3); variolation scars were found in only 5 out of 363 children under 5 years. Even in areas in which a systematic vaccination campaign had not yet been conducted, almost half of the people had vaccination scars and only 23% were unprotected. In nomadic groups, however, only 25% had vaccination scars, nearly 40% had scars of variolation, and 29% remained fully susceptible. The results were encouraging but, at the same time, they had to be interpreted with reservation. Because of time constraints, the assessment teams conducted their surveys in the more accessible areas. Thus, the data undoubtedly indicated a higher level of protection and less variolation activity than might have been expected in the more remote mountainous areas.

Table 14.3. Afghanistan: results of scar surveys in 13 provinces by the WHO assessment team, by age group, August 1969

Type of scar	% previously infected with vaccinia or variola virus, by age group (years)					Total
	< 1	1-4	5-14	≥ 15 (males)	≥ 15 (females)	
<b>Areas in which systematic vaccination campaign had been completed</b>

Unprotected	84	63	18	20	16	29
Number examined	19	86	137	111	107	460

Many recommendations were made by the assessment team and gradually, over the next 6 months, order began to emerge. The system of payments improved, greater authority was given to the director of the programme and the pace of operations in the zones increased. Nevertheless, zone directors came and went every few months; the turnover of vaccinators remained depressingly high, as they were regularly summoned for military duty or left for other jobs; efforts to utilize the vaccinators assigned to provinces proved futile.

#### *Methodology of the vaccination campaign*

The vaccination campaign was simple in concept but required imagination to execute. Five-man vaccination teams moved systematically through the country, completing their task district by district and province by province. The teams worked for a period of 24 consecutive days, followed by 7 days' holiday. The senior supervisor, moving in advance of his team, contacted each district and sub-district political head and, finally, each village chief to explain what the teams were doing and to solicit their cooperation in ensuring that on the day of the team's visit, the male heads of household would be at home and would agree to let the adult females and children in their household be vaccinated. In most parts of the country, it was possible to vaccinate families only if permission was given by the male heads of household and such vaccination had to be done in the house. The supervisor also explained the hazards of variolation and endeavoured to seek out practising variolators. Variolators, when identified, were sometimes recruited as vaccinators or offered a free supply of vaccine to be used in place of scab material.

A performance goal of 100 vaccinations per vaccinator per day was established. The number was not large, but reasonable considering that many villages could be reached only after hours on foot or horseback, after which each household head had to be individually contacted and his permission obtained to perform vaccination. By the end of 1969, the goal had been achieved by most teams. Initially, the numbers of vaccinations performed were tallied by age group and sex but the vaccinators found it inconvenient to carry paper and pencils and to tally each vaccination performed. A simpler method was adopted. When a team completed work in a village, it simply counted the number of needles used

and recorded it, along with the date and the name of the village. The completeness of coverage by age group was determined 1-3 weeks later by an assessment team.

To conduct a systematic vaccination campaign such as this required accurate and detailed maps, but it was soon discovered that the maps provided by the Cartographic Institute and the Malaria Institute omitted many villages and misplaced others. To cope with this problem, the team leader asked each village leader to identify each neighbouring village and its location. These were then added to the map and the map redrawn when necessary.

#### *Methodology for the assessment of vaccination coverage*

Assessment of the performance of the vaccination teams played an especially crucial role in the success of the Afghan programme. An assessment team composed of 2 persons visited a 10% sample of the villages 7-10 days after vaccination to determine the proportion of people vaccinated. Assessment was a new concept that was not readily accepted by the national health authorities. It seemed wasteful to them to assign 2 responsible supervisory staff merely to check the performance of others. They argued, moreover, that if assessment was to be carried out, all persons in every village would need to be examined, an impossible task given the limited resources available. Only with difficulty was it possible to persuade the health authorities of the value of a sample assessment which measured the overall performance of a team in a geographical area.

If only some villages were to be visited, which ones should be selected? One approach would have been to use standard statistical sampling methods, which require that every person has an equal chance of being included in the sample. The correct procedure would then have been to take into account the size of the population in each village in drawing the sample. Given the educational level of the staff, this was considered too complex. Another approach would have been simply to ask the teams to assess 10% of the villages in each geographical area. If this had been done, only the most accessible villages would have been checked, and these would have been the villages that the vaccination teams would also have visited. Not only would a falsely high level of vaccination coverage have been

recorded but remote villages in which variolation was prevalent would have been missed. Another scheme was adopted. The name of each village in which vaccination had been performed was written on a piece of paper that was then placed in a box. The assessment team leader drew from the box a number of papers equivalent to 10% of the total, and each of the villages thus selected was then assessed. The process itself was readily understood and it helped to ensure that at least some of the less accessible villages were checked.

To facilitate assessment, a simplified form (Plate 14.3) was developed by Dr Keja and Henderson with the assistance of Mr Svend Brøgger, a WHO statistician assigned to the Public Health Institute in Kabul. It was decided that in each village chosen for assessment, 85 children under 15 years of age and 60 adults should be examined. Children were the more important group, because it was among them that most cases were occurring. They were also the age group more likely to be encountered when the team visited a village. Because adult levels of immunity were found to be consistently higher owing to previous smallpox or to variolation or vaccination, the assessment of adults was later abandoned. The recording form had 145 boxes, 10 for the age group under 1 year, 30 for the age group 1-4 years, 45 for the age group 5-14 years and 60 for the adult group aged 15 years and over, a distribution roughly approximating to the age distribution of village populations.

The assessor was instructed to begin at one end of the village and to proceed house by house until a sufficient number of persons had been examined so that each box would contain a mark. In examining an individual, he looked first at the face. If there were pockmarks, he recorded a "P" in the box and proceeded to examine the next person. If there were no pockmarks, he looked for a variolation scar on the forearm or wrist. If it was present, he marked a "V" in the box. If neither was present, he looked for a vaccination scar and if he found one recorded an "X", or "XX" if it was a primary take. If none of these scars was present, he recorded a "O". He then asked each individual whether he or she had been vaccinated by the team. If the answer was affirmative, a dot was placed within the "O". When assessment was complete, the numbers of different symbols were summed and a simple calculation was performed. Absentees were tallied at the bottom of the sheet; if they

were found to be numerous, the assessment was considered invalid. Experience showed that each team could carry out assessments in 2 villages every day.

With this assessment technique, it was possible to determine the immunity level in the village, the proportion of successful vaccinations, the extent of variolation and the past history of smallpox. The work sheet as well as the final report filled up only one side of a sheet of paper. From the physical condition of the report sheet, it was possible to know whether or not the team had actually performed the assessment: a clean form with all symbols neatly inscribed suggested that the data were contrived.

The method of assessment was not what a traditional statistician would have prescribed and the sample was certainly not "statistically valid". However, it was understandable to field staff and provided important information. As such, the sample came to be known as "operationally valid". Eventually, it was adapted for use in many other countries.

Operationally, the goal was established that at least 95% of primary vaccinees should show evidence of a successful vaccination and that not more than 20% of the children under 5 years of age should remain susceptible after a team had vaccinated in a village. Invariably, much higher levels of protection were found among individuals over 5 years of age. Thus, if fewer than 20% of those under 5 years remained susceptible, the overall proportion of susceptible people in the village would be much lower than this, usually less than 10%. If the assessment team found that more than 20% of children under 5 years were susceptible or that the proportion of successful vaccinations was unsatisfactory, the vaccination team was obliged to return to the area to revaccinate the population of all the villages, but its members were not paid a travel allowance. Within months after the assessment teams began work, the proportion of susceptible young children remaining after mass vaccination dropped abruptly from a range of 20-40% to consistently less than 10% and often less than 5%.

### Progress in the Vaccination Campaign

Because of the host of administrative problems and the lack of transport, progress in the vaccination campaign remained unsatisfactory during 1969 (Table 14.4). Only

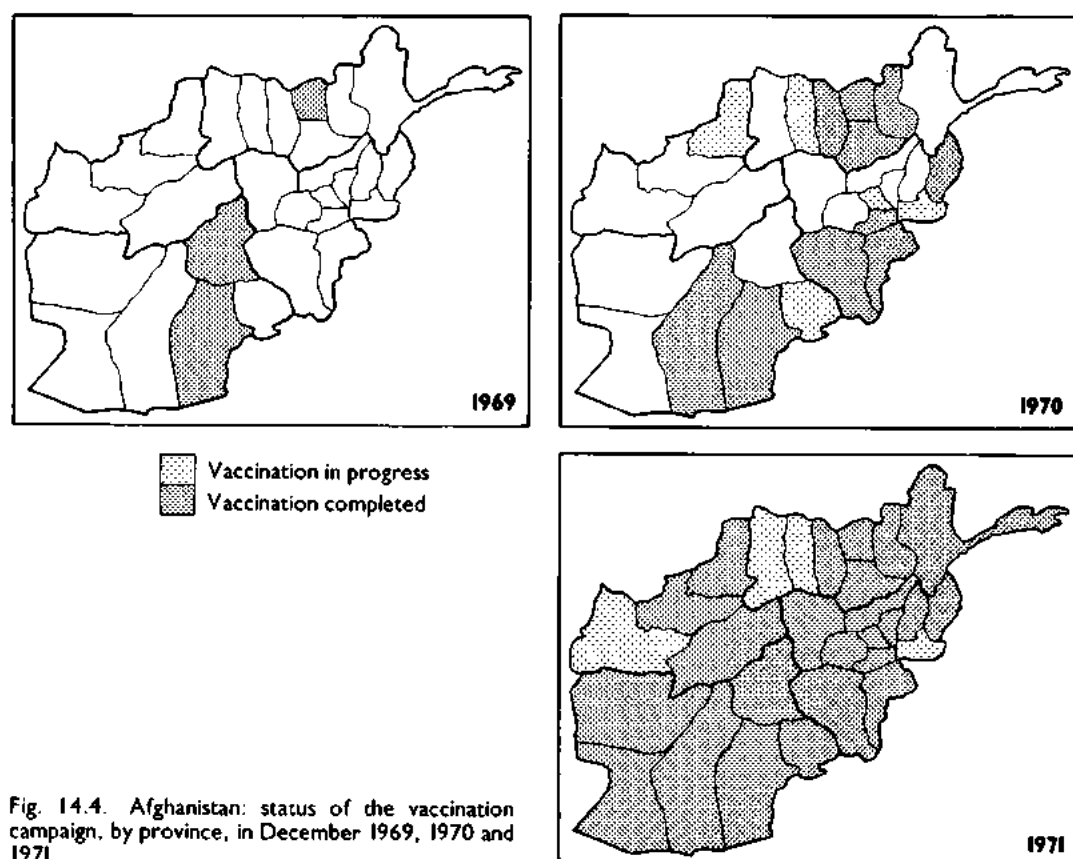

Fig. 14.4. Afghanistan: status of the vaccination campaign, by province, in December 1969, 1970 and 1971.

Total	4	4	20	232	38	298

1970, 3 541 643 vaccinations were performed and work was completed in 10 provinces (Fig. 14.4). Activities extended to Herat, the 4th zone, in 1971 and 4 676 442 vaccinations were performed during the course of the year. By the end of 1971, campaigns had been carried out in all but 4 provinces, and by June 1972, the first round of vaccination had been completed. In all, 10.5 million people had been vaccinated by a staff which at its maximum numbered only 298 persons (Table 14.5). The population of Afghanistan in 1972 was estimated by the government to be 17 million but, in the absence of a census, the actual number was unknown. The data of the smallpox eradication programme suggested that a population estimate of no more than 12-15 million persons would be more realistic.

On completion of the first round of vaccination, it was decided to undertake a second round, but to vaccinate only those under 15 years of age. The objective of this round was not so much to improve the immune status of the population as to ensure the continued mobility of the vaccination teams, who could both search for cases and detect the presence of variolators in the course of their work. The second round of vaccination was completed in 18 months, during which 5.4 million persons were vaccinated (see Table 14.4). The shorter time required reflected, in part, more efficient programme operations; of greater significance was the fact that village leaders were far more helpful and the villagers more receptive. After the second round of vaccination had been completed, it was decided to perform yet a third round, again to ensure a continuing search for cases and the detection of variolators. During the third round, only children under 5 years of age were vaccinated. This phase of vaccination was completed in just over a year, during which 1 621 774 individuals were vaccinated. Cooperation had progressed to such an extent in some areas that villagers assembled young children at collecting points, thus obviating the need for vaccinators to visit each house.

The nomadic and semi-nomadic Kuchis, who were estimated to number more than 2 million, presented a special problem. Entire families wintered in lowland pastures in southern Afghanistan and Pakistan, and, with their herds, moved to upland pastures in the spring. On the way, they travelled in large bands along comparatively well established routes, but once settled, they scattered widely,

often in virtually inaccessible areas. Although, when settled, they readily accepted vaccination, they resisted it while travelling, fearing reactions to the vaccine. Many were vaccinated during the course of the systematic campaign but, as shown in a survey of Kuchis in Helmand Province in 1971, vaccinal immunity differed greatly from one group to another (Table 14.6). To ensure more complete coverage, a special summer programme was conducted during 1973 in Ghor and Bamian Provinces, in which the largest proportion was settled.

At the conclusion of the second round of systematic vaccination in 1973, the overall levels of vaccinal immunity in Afghanistan were assessed during a special programme. The levels of protection were among the highest found in any country (Table 14.7).

### A Smallpox Surveillance Team

The investigation of a rumoured outbreak in November 1970 in the mountainous province of Oruzgan illustrates the pride and dedication that the teams developed. A team was sent on horseback to elicit information about the outbreak. On its way up a mountain, it encountered metre-deep snow and was forced to turn back. The team then approached the area by another route. Again, it encountered snow; the horses were abandoned and the team members continued on foot for 4 days to get to the villages. They stayed in the villages, moving from one to another to vaccinate. In all they spent 6 weeks vaccinating the inhabitants of villages in the middle of winter in the Oruzgan mountains. When it was possible to carry out a thorough search of the area in the spring, no cases of smallpox were found.

### The Elimination of Smallpox: Epidemiological Patterns, 1969

Given the many problems and obstacles, the rapid development of a highly effective campaign of systematic vaccination was an extraordinary achievement. Programme staff, however, undertook at the same time an equally effective effort to improve reporting and to investigate and contain outbreaks. They decided that from September 1969, every reported case of smallpox would be investigated by a zonal containment team, usually accompanied by senior national and WHO staff. The Afghan programme was one of the very few in which both mass vaccination and surveillance-containment measures were simultaneously and successfully conducted.

To improve reporting, provincial medical offices were directed by the Minister of Health to report any suspected case by telephone or telegraph either to the national smallpox eradication office in Kabul or to the zone office. At the same time, the President of the Malaria Institute directed all malaria workers to report cases of smallpox. Meanwhile, programme staff began regular visits to each hospital, health centre and clinic to explain the programme and to ask that every suspected case or rumoured outbreak of smallpox should be reported promptly. Because only 69 out of 326 subdistricts had a health unit and because the malaria programme was not operational throughout the country as a whole, and not notably effective, additional measures were required. Zonal surveillance teams began systematic visits to the subdistrict civil authorities, the *maliks* and *arhabs*, to solicit their help and to visit the few

existing schools. Each report of a case was investigated promptly by a surveillance team. The promptness of response provided tangible evidence to those reporting that the programme personnel were genuinely interested in receiving reports, and this gradually became widely known. Indeed, some villages which sought vaccination sent false reports, knowing that the report of a case would quickly bring a surveillance team to the village.

During the last 4 months of 1969, 22 reports of smallpox were received, of which 20 were verified to be outbreaks. In all, 79 cases were reported but the surveillance teams found an additional 171 cases during investigation (Table 14.8). In the course of 1970,

### Definition of a Case of Smallpox among Variolated Persons

All persons who had been successfully variolated should properly have been recorded as cases of smallpox since they had been infected with variola virus. If all such individuals had been counted as cases, the recorded incidence in Afghanistan would have been high indeed, because in some outbreaks variolators performed upwards of 100 inoculations. To decide whether a person had been successfully variolated, however, was not a simple matter. The primitive technique of variolation often produced serious bacterial infections and it was impossible to tell whether or not variola virus had grown in the skin. For Afghanistan, and similarly for Ethiopia (see Chapter 21), it was agreed by WHO and the national authorities to record as cases only the variolated individuals who exhibited smallpox lesions on other parts of the body as well as at the site of variolation. It was recognized that some who were successfully variolated would have a lesion only at the site of variolation and thus there would be an underenumeration of cases. However, because the probability of smallpox transmission was correlated with the extent of rash, such individuals were much less likely to transmit infection and therefore less important epidemiologically.

with reports being received from many additional sources (Table 14.9), the number increased to 1044 cases in 83 outbreaks. This was the highest total of cases recorded in Afghanistan since 1955. Cases were recorded

in 21 of the 28 provinces (Table 14.10) and, as was the case in other countries, the apparent epidemic of smallpox (Fig. 14.5) alarmed the national authorities and fostered substantially greater support for the programme.

Fig. 14.5. Afghanistan: number of reported cases of smallpox, by month, 1969–1973.

Special concern was caused in 1970 by the increasing number of cases in the city of Kabul, and a number of outbreaks in other provinces which were traced to this source. In all, 156 cases (15% of all cases in Afghanistan) were reported from Kabul, most of which occurred in the congested poorer quarters of the city in which visitors from rural areas often stayed. Originally, vaccination in Kabul had not been planned since extensive vaccination campaigns had repeatedly been conducted there between 1962 and 1968. Because of the outbreaks, however, a special campaign was carried out during the winter months of 1970–1971. As in many other cities, the infectious diseases hospital itself proved to be a problem, 5 of the outbreaks resulting from the spread of smallpox within the hospital. One of the people infected was a Danish student, admitted because of suspected typhoid fever, who developed smallpox after returning to Copenhagen (see Chapter 23). This problem of hospital infection was eventually solved when smallpox eradication staff were assigned to the hospital to ensure the isolation of patients and the vaccination of all people admitted, for whatever reason. With these measures, Kabul and its infectious diseases hospital ceased to be a problem.

The number of outbreaks increased from 83 in 1970 to 107 in 1971, but only 736 cases were found on investigation, substantially fewer than the 1044 cases recorded in 1970.

In 1972, outbreaks were reported in only 11 provinces and the numbers of cases and outbreaks diminished rapidly. Between January and June, 10 provinces recorded 196 cases in 39 outbreaks. After June, smallpox was detected only in the southern provinces of Oruzgan, Kandahar and Zabul, the last indigenous cases occurring in Oruzgan in September, just 36 months after the surveillance–containment programme began. Later in the year, 1 outbreak occurred in Zabul and 2 in Kandahar whose sources of infection were, respectively, the towns of Pishin and Quetta, both in Pakistan.

### The Final Outbreaks

Between October 1972 and April 1973, no evidence of endemic smallpox was found despite active search and the investigation of many rumours. However, 3 more outbreaks were yet to be discovered: 2 in April and 1 in June. The following brief descriptions of these outbreaks and how they were dis-

Fig. 14.6. Afghanistan: sources of infection and location of outbreaks, 1973.

covered, investigated and contained illustrate some of the challenges experienced by the Afghan staff.

#### *Ghazni Province, Abramhel village*

On 10 April 1973, a mobile vaccination team heard rumours from villagers of suspected cases in Wor Subdistrict, 85 kilometres away. The team leader and his supervisor went to the area the following day and in the village of Abramhel, 5 kilometres from a barely motorable road, found 3 active cases and 3 close contacts with fever, and learned of a person who had died of the infection. The village, consisting of 9 households and 56 persons, was one of a number of small, widely scattered villages situated on barren mountain slopes rising above an arid plain. A search of this and 12 neighbouring villages began immediately along with containment vaccination. In all, 2411 persons were vaccinated. Systematic vaccination had been conducted throughout the area 3 years earlier but this group of villages had been missed. The first case was that of a 23-year-old man who had travelled some 600 kilometres to the town of Sukkur in Pakistan in search of work (Fig. 14.6). He arrived back in his village after more than a year's absence, became ill with smallpox and died. In all, 13 cases eventually occurred, 2 of whom had old variolation scars and 7 of whom were vaccinated during the incubation period. Three of these persons died.

#### *Zabul Province, Senkay Wolesswali (district)*

Fearing that Kuchi nomads might reintroduce smallpox during their spring migration from Pakistan, smallpox eradication teams in 1973 endeavoured to intercept groups of Kuchis in order to detect cases and vaccinate the others. On 29 April, a surveillance team found a 10-year-old child with smallpox among a group which was travelling from Pishin in Pakistan to its summer home in the mountainous province of Oruzgan. Only 5 of 140 persons in the group had not been vaccinated; the patient was one of the unvaccinated. The boy and his mother were isolated in the zone office and 2 vaccinators were assigned to travel with the Kuchis to detect any further cases that occurred. The Kuchis, who were smuggling cloth, feared that they might be reported and left silently, leaving the mother and child and 2 sleeping vaccinators. Angered by this, the mother revealed the intended route and destination of the band, and a vaccination team again intercepted them to keep them under surveillance for 6 weeks. No further cases occurred.

#### *Kandahar Province, Nes Subdistrict*

As happened in several countries, the final outbreak was marked by delays and failures in reporting in what was then thought to be a reasonably effective system of notification and containment. On 3 July 1973, the zone office in Kandahar was informed that a number of deaths had occurred in a Kuchi nomad camp some 90 kilometres to the north. Five days had elapsed since the commandant of police at Nes had telephoned this information to police headquarters in Kandahar. The provincial medical officer was notified the same day and he immediately sent a laboratory technician to investigate. The technician returned on 30 June to confirm that the outbreak was smallpox. Instead of directly informing the zone office, a few blocks away, the provincial medical officer wrote a letter to the office on 2 July which was received late the next day. On 4 July, the zone team went to Nes, where they found a Kuchi camp of 45 persons living in 7 tents. In all, 11 cases with 5 deaths had occurred. Surprisingly, a local malaria surveillance agent had visited the camp several days earlier, vaccinated a few people and departed without notifying anyone. Meanwhile, on 2 July, a variolator who lived in Nes had visited the camp, gathered scabs from one of the patients, variolated 10

persons and departed for another province. The team conducted an immediate search and vaccinated the population of the subdistrict, performing some 2300 vaccinations in all. Nine of the 11 cases were among adults. Systematic vaccination had been completed in the subdistrict only 3 months before, but at the time of the team's visit, only the children and a few women had been in camp, the men having gone far ahead to prepare the next campsite. The first case in the outbreak had been that of a 35-year-old man who had accompanied his uncle to a hospital in Quetta, Pakistan, and had developed smallpox after his return. A cable to Quetta confirmed that at the time of his visit, cases were present in the hospital. Thus, the last known outbreak in Afghanistan was traced to infection probably acquired in a hospital; the report of the outbreak and its containment were delayed by a full 5 days because of poor communication; a health worker who should have reported the cases failed to do so; the men in the camp who should have been vaccinated only 3 months earlier were missed because they had travelled to another area; and a variolator was given the opportunity to acquire scabs. Despite extensive search the variolator was never found nor was another case of smallpox detected in Afghanistan.

### Conclusion of the Programme

The last outbreaks in Afghanistan were cause for celebration, but with smallpox still endemic in Pakistan and with the spectre of its possible recurrence through the practice of variolation, programme staff could not relax their efforts. The tens of thousands of nomads who began their annual trek northwards out of Pakistan in late February and March were of particular concern. In 1973, the number of surveillance teams in southern Afghanistan was increased and a special programme was begun to intercept nomads during their travels. During this period, different surveil-

lance teams succeeded in intercepting some nomadic groups so often that the leaders of the groups protested against the harassment. To deal with the problem, it was decided to issue a special certificate to the leader after all members of a group had been examined, provided that they all accepted vaccination. When subsequently intercepted by another surveillance team, the group leader simply presented the certificate, assuring the nomads of the right of passage without further examination. Happily, the procedure was well accepted.

Meanwhile, the systematic vaccination campaign was continued, primarily to sustain a continuing search for cases but also to keep the number of susceptible persons as low as possible and so diminish the chance of variolation being revived. In fact, as late as 1976, evidence of attempted variolation was found, but no successful variolations are known to have occurred following the last outbreak in 1973.

Finally, after the interruption of smallpox transmission in Pakistan in October 1974, a reward of 1000 afghanis (US\$18) was offered to anyone reporting a case. The number of rumours and reports of suspected cases increased dramatically but, on investigation, none proved to be smallpox.

### Epidemiological Data

Data on age and vaccination status are available for 2258 of the 2291 cases that occurred between 1969 and 1973 (Table 14.11). Of the total, 360 cases (16%) were among persons infected through variolation. Only 83 (4%) occurred among those who had been vaccinated before exposure.

Because of the isolation of so many villages and areas in Afghanistan and the difficulty of movement from place to place, it was expected that a much larger proportion of cases would be found among adults, but in fact the proportion was not much greater than in

Table 14.11. Afghanistan: reported number of cases of and deaths from smallpox, by age group, 1969-1973<sup>a</sup>

Age group (years)	Cases		Number naturally infected		Number variolated	Number of deaths

**Plate 14.5.** **A:** A nomad encampment in the vast, sparsely settled central mountain plateau of the Hindu Kush, Afghanistan. **B:** A Pakistani woman waves the traditional *neem* leaves over a sick child. Throughout much of the Indian subcontinent, the leaves of the *neem* tree were believed to have special healing powers over smallpox.

Indonesia (11%), with its dense population, and far smaller than in Pakistan (37%). The paucity of susceptible adults reflects the extent of previous smallpox and variolation.

The overall case-fatality rate of 13.8% (313 deaths among 2258 cases) understates the severity of natural infection, including, as it does, 360 cases infected by variolation, among which the case-fatality rate was often 2-3%. Discounting variolation, the case-fatality rate was about 16%, a figure approximating to that found in the Indian subcontinent.

The source of infection of the 237 outbreaks that occurred from 1970 to 1973 is shown in Table 14.12. Of the 201 outbreaks for which a source could be identified, 45 (22%) represented importations from Pakistan and 47 (23%) resulted from variolation. During this 4-year period, the teams investigated a further 345 outbreaks reported to be smallpox but which, on investigation, proved to be chickenpox (202), measles (51) and other skin infections (43). The remainder were rumours without apparent foundation.

Table 14.12. Afghanistan: sources of infection of outbreaks, 1970-1973

Source	1970	1971	1972	1973	Total
Pakistan	11	13	18	3	45
Variolation	23	21	3	0	47
Other sources in Afghanistan:					
Nomads	8	4	5	0	17
Hospitals	5	2	0	0	7
Other	16	55	14	0	85
Unknown	20	12	4	0	36
Total	83	107	44	3	237

Outbreaks which resulted from importations, with one exception (in Badakshan Province), occurred in areas south of the Hindu Kush mountain range in provinces near or on the border with Pakistan. Similarly, outbreaks traced to the nomads (except those in Badghis Province) who migrated from Pakistan to Afghanistan were in these same areas (Fig. 14.7).

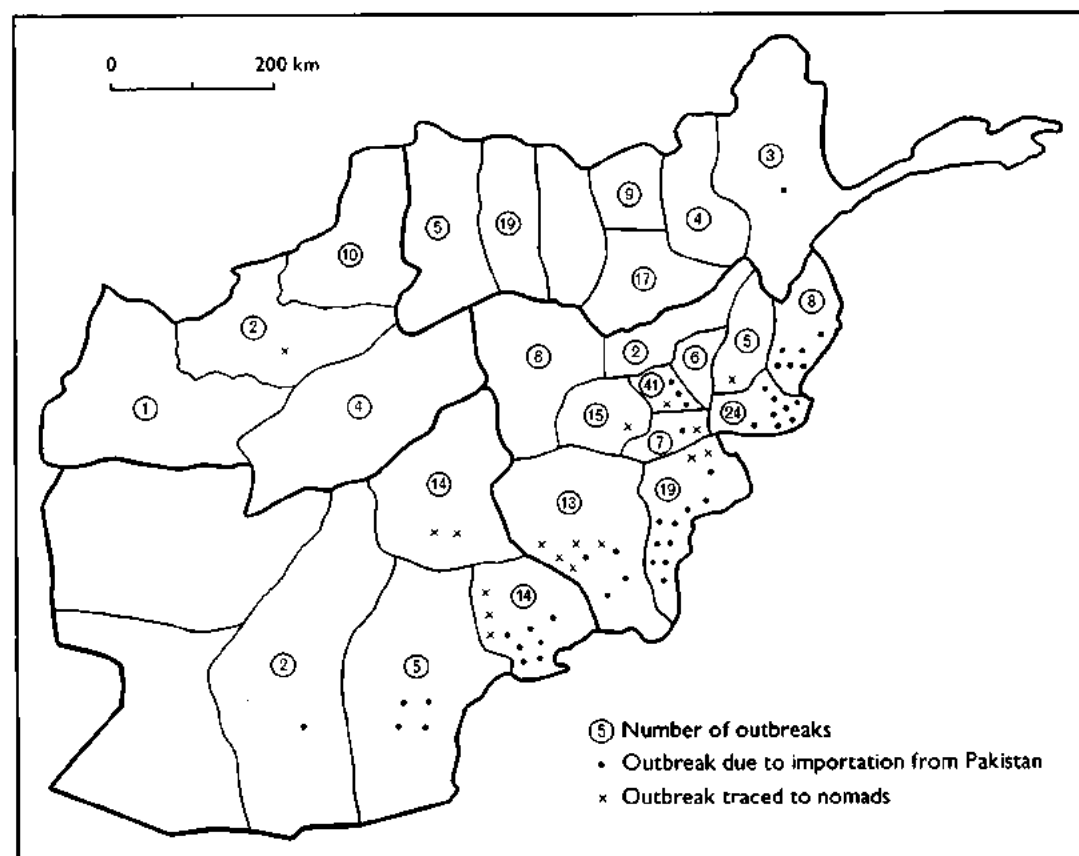

Fig. 14.7. Afghanistan: number of outbreaks by province and location of those caused by importations from Pakistan and those among nomads, 1969-1973.

Delays in the detection of outbreaks (Table 14.13) were a problem throughout the programme. The mean interval was just under 4 weeks, the delays being as great in 1972 as they were in 1969-1970. After the outbreaks had been found, however, further transmission did not continue for long. In only 6 out of 224 outbreaks did new cases occur more than 2 weeks after containment had begun, even though many of the outbreaks were on a large scale (Table 14.14).

### The Problem of Variolation

Variolation had been thought to be a major, perhaps insoluble, problem. The practice was most widespread in the more remote mountainous villages and among the nomadic Kuchis, its extent being in inverse relation to

the people's ease of access to vaccination. Among the adults in some areas, upwards of 50% bore the scars of variolation. For some, variolation was the only available protection against naturally occurring smallpox and many continued to pay to have variolation performed, even when free vaccination became available. Variolation was a familiar procedure to them and they regarded it as providing permanent immunity.

Priority was given to the identification of variolators: to characterize them, learn about their practices, obtain variolation material from them and persuade them to abandon the practice or to accept vaccine for use instead of variola virus. This was difficult, however, because they feared punishment if they were discovered. Between 1969 and 1973, 61 variolators were contacted and persuaded to abandon the practice. Later, in 1976, a special search for variolators revealed 36 others. The location of the variolators by province is shown in Fig. 14.8. Undoubtedly the numbers found represent only a small fraction of the total.

The variolators performed variolation only on the request of a village or a family, and usually for a fee. Many were farmers and some were religious leaders; other practitioners who were identified included a tailor and 4 women. In almost all cases, the variolator's father and grandfather had also been variolators and usually only the eldest son was engaged in the practice. Scabs—rarely pustular material—were collected from a recovering patient, preference being given to patients with many lesions who could therefore provide a greater amount of material. None of those interviewed said that they selectively sought to obtain scabs from less severe cases on the assumption that virus from such cases might result in less severe reactions. The scabs were usually kept either as such or in a powdered form. Sometimes, a liquid (e.g., honey or spices in water) was added either soon after the scabs had been obtained or immediately before inoculation. Because variola virus is exceptionally stable when dried, especially if kept in a cool place, efforts were made to learn from the variolators how long they believed they could satisfactorily store the virus. Most of them stated that it was necessary to obtain new material each year. A few observed that material could be retained for as long as 2 years, but they noted that such material was not reliable and often did not induce the desired infection.

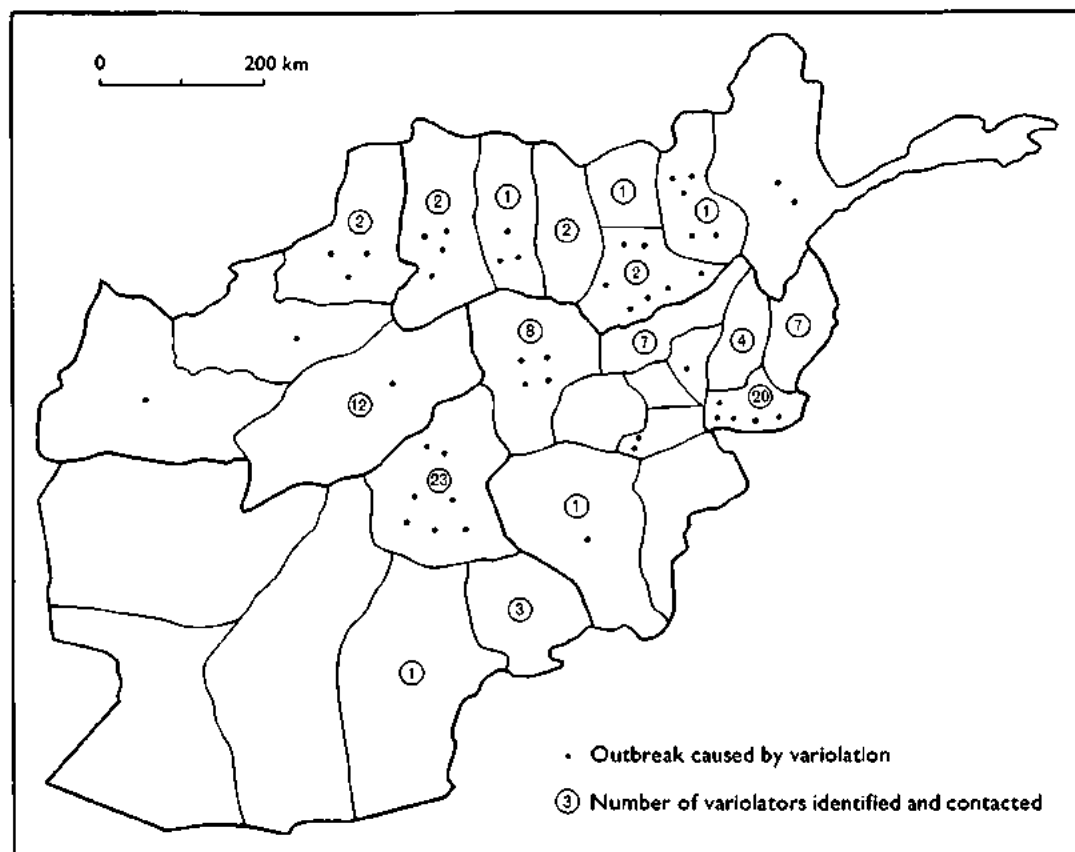

Fig. 14.8. Afghanistan: location of variolators who were identified and of outbreaks caused by variolation.

The variolators kept the scabs in all manner of jars and boxes, usually in their houses. A particularly interesting case was that of a variolator who kept the material in a horn, stored in a cave at a high altitude, quite far from his home. Although storage in a cold environment such as this should have served well to preserve the virus, the variolator reported that the material he collected was not very effective if more than a year old.

Six specimens were obtained and tested in WHO reference laboratories. Variola virus was isolated from 4 of them, of which 2 had titres that were presumably high enough to induce infection if inoculated (Table 14.15). The 4 specimens from which virus was isolated were collected between March 1969 and April 1970. One specimen collected in April 1976 consisted of scabs said to have been obtained in Pakistan in October 1974. In this specimen, virions were seen by electron microscopy but the virus did not grow on egg membrane.

Variolators were usually known to villagers throughout a subdistrict or district and were summoned only when smallpox began to occur in the area. However, some variolators travelled considerable distances, offering their services to the headman of each village visited. Sometimes, all the susceptible individuals in an entire village were systematically vaccinated, ensuring that none would remain to be exposed to natural infection acquired from those who had been variolated. This was the exception rather than the rule, however.

The usual method of variolation was to suspend the powdered scab material in a paste and to inoculate it either on the dorsum of the forearm or on the wrist, adjacent to the extensor tendon of the thumb (referred to by physicians as "the anatomical snuffbox"). Some did this by superficial linear scratch using a knife and some by multiple puncture using a small bundle of needles. A bandage was then placed over the area. Fever began on

about the 4th or 5th day and a lesion appeared on the 7th day. Many of those inoculated developed lesions elsewhere on the body and, although the variolators who were interviewed usually denied that any of their patients had more than 100–200 lesions, surveillance teams found some with more extensive rashes and learned of others who had died.

Between 1970 and 1972, 47 out of 237 outbreaks were caused by variolation. These

occurred primarily in provinces lying north of the Hindu Kush range and in the central mountainous provinces of Bamian and Oruzgan (Fig. 14.8). As is shown in Table 14.16, 714 cases occurred in outbreaks which had been initiated by variolation—i.e., more than one-third of all cases in Afghanistan during this 3-year period.

Certainly, variolation was a problem, but considering the large number of traditional variolators, it was less serious than had been

WHO/P. ALMASY

Plate 14.6. A variolator demonstrates the traditional way of binding the site of inoculation after variolation. The picture was taken in Afghanistan in 1970.

Table 14.16. Afghanistan: number of cases of smallpox due to variolation, 1970-1972

	1970	1971	1972
Number of outbreaks initiated by variolators	23	21	3
Number of cases due to variolation	120	200	16
Number of additional persons infected in the outbreak	213	158	7
Total number of cases directly or indirectly due to variolation	333	358	23

Proportion of cases related to variolation	32%	49%	10%

expected. Because vaccination was known to most of the population—though it was not always easily available—variolation had already begun to disappear by the time the programme in Afghanistan commenced. The efforts of the surveillance teams to contact all village and subdistrict leaders and to explain to them the adverse consequences of variolation undoubtedly helped to diminish the practice. The immediate response of the surveillance teams to any reports of smallpox cases was also important: vaccination was made widely and freely available before the variolators were able to initiate their activities.

## PAKISTAN

Pakistan and its smallpox eradication programme presented a contrast to the situation in Afghanistan. Most of West Pakistan's 60.5 million people (1967) lived in the vast Indus river plain and in the Himalayan foothills, where population density was high. The government structure throughout this area was comparatively sophisticated, health services were much more extensive and health personnel were far more numerous than in Afghanistan. A network of roads, as well as train and air connections, and postal and telegraph services facilitated communication. Throughout this area, a programme of smallpox vaccination had been in operation for nearly 100 years; vaccinal immunity was high and variolation was all but unknown. Some remote, sparsely populated areas, however, presented problems almost as formidable as those in Afghanistan. In the northern mountainous areas of Gilgit and Azad Kashmir, in the mountainous districts bordering on Afghanistan and in the vast western

deserts of the Baluchistan plateau, government and health services were less well developed, health personnel were few, vaccination had been less extensively practised and a few persons were still being variolated. The inhabitants of such areas, however, constituted no more than 10-15% of the country's total population.

In 1967, Pakistan consisted of the provinces of West Pakistan and East Pakistan, separated by the breadth of India and, each essentially autonomous so far as health programmes were concerned. In July 1970, the government decided to divide West Pakistan into 4 provinces and 2 federal regions. Health continued to be a provincial responsibility, the Federal Ministry of Health retaining authority only for health policy, the direction of medical research, standards of medical education and relationships with international organizations. A single smallpox eradication programme in West Pakistan thus became 4 separate and autonomous provincial programmes and 2 federal regional programmes which differed greatly in their methods of operation, rate of progress, and degree of political commitment to eradication. What little coordination existed between the programmes was achieved primarily by the WHO advisers. In December 1971, East Pakistan became the independent country of Bangladesh, whose programme is described in Chapter 16. The present chapter deals only with West Pakistan, designated, since 1971, as Pakistan.

Because of the availability of resources and the more sophisticated government and health structure, the eradication of smallpox appeared to be more feasible in Pakistan than in Afghanistan. Surprisingly, transmission was not interrupted until October 1974, 2 years later than in Afghanistan. Even when the last cases were being detected, the case notification procedure and surveillance system were still so inadequate that many months were to elapse before either national or WHO staff were persuaded that eradication had been achieved. Adherence to traditional mass vaccination, erratic political commitment and poor management were to characterize the programme throughout most of its course.

### Smallpox before 1967

As in Afghanistan, only variola major, the severe form of smallpox, is known to have

occurred in Pakistan; and in past centuries, variolation had been widely practised. Smallpox control through vaccination began during the colonial period, before British India became the independent countries of Pakistan and India, and was widely practised throughout the more populous areas until the late 19th century. In the former province of Punjab, which constitutes a major part of Pakistan, a large-scale programme of vaccination began in 1875 under a General Superintendent of Vaccination, who employed 29 supervisors and 121 vaccinators. A Vaccination Act was passed in 1880, and in 1888 local government bodies were created which were responsible for vaccination programmes in their own areas. Indeed, throughout the 1970s, vaccination by "local body vaccinators" (personnel paid by local government authorities) continued in most parts of Pakistan. Liquid vaccine produced at the Punjab Vaccine Institute in Lahore was used. The extent of vaccination is illustrated by data from the former Punjab Province for the period 1933–1938. Each year, 3.1–5.8 million vaccinations were recorded in the province, whose population was only 24.8 million (1935) (Table 14.17). Nevertheless, the number of notified cases of smallpox remained high and major epidemics recurred every 4–6 years.

Although the vaccination campaign undoubtedly had an impact on the incidence of smallpox, the effect was not impressive in comparison, for example, with that of the campaign in Indonesia, in which smallpox was eliminated during the same period. This was probably due to the fact that the vaccine used in Punjab was the thermolabile liquid product rather than the dried, heat-stable variety employed in Indonesia.

Following independence, local body vaccinators continued to vaccinate using the liquid vaccine. In the period 1959–1968 the reported number of vaccinations performed each year represented a proportion of the population ranging from 14% to 38%; moreover, the number of primary vaccinations reported to have been performed was greater than the number of newborn infants. In view of the fact that, in 1968, there was 1 vaccinator for every 40 000 persons, the numbers of reported vaccinations are believable. None the less, smallpox continued to occur, with peaks in incidence every 4–6 years (Table 14.18). As later studies were to show, the number of reported cases was only a

Table 14.17. Punjab Province of British India: number of vaccinations performed and number of cases of and deaths from smallpox, 1933–1938

Year	Number of vaccinations	Number of cases	Number of deaths
1933	3 206 356	22 571	11 626

fraction of the total that actually occurred. However, the once widely prevalent practice of variolation ceased in all but a few remote, less populous mountainous and desert areas, where it continued to exist until the end of the programme.

### Programme Strategy

Immediately after the decision of the Nineteenth World Health Assembly in 1966 to intensify the smallpox eradication programme, the Director of WHO's Regional Office for the Eastern Mediterranean, who fully supported the programme, had recruited the energetic Dr Ehsan Shafa, a veteran of Iran's successful smallpox eradication programme of the early 1960s, as the regional adviser on smallpox eradication. In March 1967, Dr Shafa first consulted government officials in Lahore to discuss the development of a programme. Separate schemes were drawn up for East and West Pakistan. The

WHO

**Plate 14.7.** After a vaccination session, Pakistani schoolchildren hold their sleeves away from their arms to allow the remaining vaccine lymph to dry off. This was the customary practice with liquid vaccine in most countries, although vaccinations were equally successful if the excess moisture was wiped off immediately. In many countries in which mass campaigns were conducted, only a small proportion of the children attended school but they were often vaccinated at 6-month intervals by vaccinators eager to fulfil the quotas set for them.

plan of operations was signed by WHO in August 1967 but not by the government until April 1968.

The procurement of supplies began in the hope that the programme might be launched by the end of 1968. A WHO adviser was assigned in September 1968 and supplies were delivered that autumn. However, the programme did not commence until June 1969. Five more years were to elapse before smallpox transmission was finally interrupted. A host of administrative problems hampered the programme from its inception, and during 1971, activities everywhere were curtailed because of the civil war. However serious these problems, the principal deterrent to progress was the protracted delay in taking cognizance of the findings of a group of investigators at the Pakistan Medical Research Centre in Lahore and of the strategy worked out by them.

The Lahore centre was supported by the government of Pakistan and the United States National Institutes of Health; it was one of four international centres for medical research and training in which United States and local scientists collaborated in medical research programmes. The investigators themselves decided which studies should be undertaken; those in the Pakistani centre decided to study the epidemiology of smallpox in West Pakistan. In May 1966, they began a 1-year study of smallpox in a rural district with a population of 1.2 million near Lahore and later undertook additional studies in urban Lahore and in other districts better to define the epidemiology of the disease (Ali & Heiner, 1971; WHO/SE/69.13, Heiner et al.; Heiner et al., 1971a,b; Mack et al., 1970, 1972a,b; Thomas et al., 1972). The studies, which are described in the next section, were the most comprehensive to be undertaken during the whole global eradication programme. The principal investigators (Dr Ashgar Ali, Dr Nusrat Fatima, Dr Gordon Heiner, Dr Muzaffar Khan, Dr Fred McCrumb, Dr Thomas Mack and Dr David Thomas) prepared a series of important papers which were distributed to WHO smallpox eradication programme staff throughout the world beginning in 1968; most of these papers were published in scientific journals between 1969 and 1972. The data argued persuasively for giving the highest priority in Pakistan to the detection and containment of outbreaks, especially during the season of lowest incidence, and to special vaccination campaigns in urban areas. The applicability of the strategy was soon supported by observations in western Africa, Brazil, Indonesia and East Pakistan, as programmes throughout the world gave increasing emphasis to surveillance and containment. Ironically, West Pakistan was among the last to commit itself fully to this strategy.

In most countries, but especially those in the Indian subcontinent, the belief that it was necessary to vaccinate every member of the population to achieve eradication was accepted doctrine. That the development of reporting and surveillance systems was at least equivalent in importance to mass vaccination was an alien concept. In West Pakistan, the principal WHO advisers up to 1971 were veterans of the successful eradication programme in Iran in the early 1960s. There, smallpox transmission had been interrupted through a large-scale vaccination campaign;

surveillance was an unknown quantity. However rational the surveillance-containment strategy might be, it was extensive vaccination to which they were committed and to which they devoted their principal energies.

Before describing the programme and its evolution in West Pakistan, it is of interest to review the findings of the group from the Pakistan Medical Research Centre, which document the status of smallpox and its epidemiology in West Pakistan at the time the programme began.

### Studies of Smallpox in West Pakistan, 1966-1967

Investigators from the Pakistan Medical Research Centre first studied the occurrence and patterns of transmission of smallpox over a 1-year period, beginning in May 1966 in a single district. Their stated objective was to determine the best strategy to interrupt transmission (Mack et al., 1970, 1972a,b; Thomas et al., 1972). Sheikhpura District, an agrarian area of 2312 square kilometres and a population of 1.2 million, of which 85% lived in 1700 villages, was selected for study. Since 1946, the district had recorded about 50 smallpox cases per annum with occasional years during which several hundred cases were reported. During the 1-year period of study, cases were identified by the epidemiologists through the field investigation of reports to the district health officer and rumours received from civil servants and travellers and through routine inquiries in villages. Control measures, if conducted, were performed by the local health authorities.

During the year of study, 146 cases in 23 villages were officially reported to the district health officer. The investigators, however, discovered 1040 cases in 121 outbreaks and subsequently estimated, by sample survey, that an additional 40 outbreaks and approximately 180 cases had occurred that had not been detected. Thus, even in this district, which had a reasonably extensive health structure, little more than 10% of all cases were being reported. The true incidence was about 1 case per 1000 population, a figure far higher than that recorded in the most highly endemic countries during this period and an incidence substantially greater than was detected subsequently in any year in any district of West Pakistan.

Data regarding the age and outcome of illness were reported for 1034 of the patients.

The age distribution and case-fatality rates were similar to those observed elsewhere in the Indian subcontinent: 29% of cases occurred among children under 5 years of age and a similar percentage (28%) among persons aged over 15 years (Table 14.19). In all, 16% died, but among infants (under 1 year) case-fatality rates reached more than 50%.

Despite the substantial number of cases, sample surveys of 15 villages showed a remarkably high proportion of persons who had previously been vaccinated. Among 6000 persons examined, 88% had either vaccination scars or the pockmarks of smallpox (Thomas et al., 1972). Three-quarters of the cases had occurred among the 12% who had not been vaccinated before exposure (Table 14.20). Among the unvaccinated household contacts of cases, 88% developed smallpox, compared with only 7% of people who had been vaccinated at some time.

More than 10 years before	65	8	12
Within preceding 10 years	115	5	4
Previous smallpox	27	0	0
Total	250	51	20

<sup>a</sup> Based on Mack et al. (1972a).

Studies of smallpox transmission in 6 rural districts showed that vaccinated persons who experienced infection transmitted the disease to others only one-fourth as often as did unvaccinated persons with smallpox (Heiner et al., 1971b; see Chapter 4, Table 4.10).

In brief, smallpox transmission was sustained primarily by perhaps 150 000 persons of Sheikhupura District's 1.2 million residents. Pakistan's vaccination campaign had been more effective, at least in this district, than had been thought. A later study, done in Lahore Municipal Corporation, showed even higher levels of protection. In Lahore, 93% of all persons surveyed showed vaccination scars or the pockmarks of smallpox. Even among infants under 1 year of age 39% were protected, and among children aged 1-4 years 84% were protected (WHO/SE/69.13, Heiner et al.; Ali & Heiner, 1971).

The seasonal fluctuation in incidence was significant (Fig. 14.9), the peak occurring during the colder, drier months of November to the end of March. By September, at the end of the hot summer monsoon, smallpox had all but vanished (Thomas et al., 1972); in the first week of September 1966, only 1 village in the entire district was infected. However, even at the peak of the transmission season, not more than 50 of the 1700 villages in the district were infected at one time.

Fig. 14.9. Pakistan, Sheikhupura District: number of reported cases of smallpox in relation to meteorological data, by 2-week intervals, 1966-1967.

The outbreaks were often small and most terminated spontaneously. Smallpox was found to spread far less readily than measles or influenza, for example. Nearly one-third of the outbreaks consisted of single cases and in only half of the 121 outbreaks did new cases develop more than 4 weeks after the first case had occurred (Thomas et al., 1972). Even when transmission did occur, an average of only 2.4 new cases was recorded during each 2-week period. The larger outbreaks were of greater epidemiological importance. More than 50% of outbreaks with 5 cases or more were identified as sources of other outbreaks, compared with only 15% of outbreaks with fewer than 5 cases.

Contrary to what many supposed, smallpox was rarely transmitted at large public gatherings or transferred from place to place by nomads. Most infections were acquired as a result of contact with the patient in his own home (Thomas et al., 1972).

A further significant observation was the identification of large urban areas as important foci for spread. Of 74 outbreaks for which a specific source of infection could be determined, 42 (57%) could be traced directly or indirectly to cities, in which only 19% of the Punjabi population resided (Thomas et al., 1972).

The group of investigators pointed out that if Sheikhupura District and the Lahore Municipal Corporation were representative of other areas with regard to vaccinal immunity levels, a mass vaccination campaign had, to all intents and purposes, already been carried out. They recommended that instead of conducting another mass campaign, attention should be focused on the detection of cases and the containment of outbreaks, especially in urban areas. Such an approach would be especially effective during the summer, when only a few localities were infected. Because the disease spread slowly within and between villages, they believed that few resources would be required to cope with the outbreaks. Even if the reporting of cases was not improved, the effective containment of those that did come to notice should have a significant impact, since, as had been found, the larger outbreaks were reported more often and were most frequently responsible for spread to other localities. Because of the importance of cities in transmission, it was reasoned that urban areas should be given priority in mass vaccination campaigns, if such were to be conducted, and that emphasis should be placed on primary vaccination.

The observations in Sheikhupura District were subsequently found to be applicable throughout most of Pakistan. Not all areas had as high levels of vaccinia immunity as Sheikhupura, but everywhere successful immunization had been far more extensive than anyone had believed and the epidemiological pattern of spread of smallpox was similar. The recommendations of the group of investigators proved to be sound when they were eventually put into practice in Pakistan in 1972.

### Beginning of the Mass Vaccination Campaign, 1968–1969

The plan of operations was signed in August 1967 by WHO and in April 1968 by the government, in Islamabad. Planning, procurement of supplies and recruitment of staff took longer than expected, but in June 1969 field operations finally began. West Pakistan, in 1969, was divided into 6 health regions, each comprising about 8 districts. Each district had a population of 1–2 million. The plan called for systematic mass vaccination campaigns in 2 regions each year. When the mass vaccination campaign was completed in a region, maintenance vaccination would be introduced to vaccinate neonates and migrants and to revaccinate the entire population every 3–4 years (Table 14.21).

The inhabitants of the two most populous health regions of Sargodha and Lahore, in which Sheikhupura District was located (Fig. 14.10), would be the first to be vaccinated. The campaign was to be directed by 2 provincial medical officers assisted by the WHO adviser and, at each health region

office, by 2 medical officers, plus supporting clerical staff. At the health region level, a unit composed of 10 vaccinators and a superintendent of vaccination were to undertake surveillance activities and to control epidemics. The primary operational unit was the district, in which the campaign was to be directed by a full-time medical officer, a district superintendent of vaccination and teams of 10 vaccinators. A complement of 50 vaccinators for every million persons was considered necessary. This number was determined on the assumption that each vaccinator would perform an average of 100 vaccinations a day over 200 working days each year. Each operational group of 50 vaccinators would have a group leader and 5 assessors to check performance; vaccination was to be conducted village by village and house by house, the inhabitants of each locality to be vaccinated systematically by an operational unit of 10 vaccinators. The units would continue work in a locality until a number equivalent to 85–90% of the estimated population had been vaccinated. As in Afghanistan, the plans called for the teams to spend 24 consecutive days in the field, followed by 7 days' leave. A 10% sample of the vaccinations performed was to be assessed 1 week after vaccination. In addition to the surveillance–containment unit at regional level, a 10-man surveillance and containment unit was to be established in each district. The projected manpower required and the number available as at December 1968 are shown in Table 14.22.

Table 14.21. West Pakistan: plan for mass vaccination campaign—number of vaccinations to be performed each year, (thousands)

Vaccinators	1 170	1 097	73
Others	47	27	20
Total	1 412	1 237	175

WHO agreed to provide US\$200 000 in support of the programme, for the purchase of 25 Land Rovers, 125 motor cycles, 1300 bicycles, 25 refrigerators, a stock of bifurcated needles, and miscellaneous supplies. (Eventually WHO provided approximately US\$1.3 million to the programme, as well as 70 million doses of vaccine (Table 14.23).) Freeze-dried vaccine produced at the Institute of Public Health, in Dhaka, East Pakistan, was to be used. It was calculated that the government of West Pakistan would need to increase its budget for smallpox eradication from 1 334 650 rupees to 2 728 480 rupees (US\$278 800–570 000) for each of the 3 years of the Intensified Programme. It was expected that the previous level of financing would be adequate to cover the maintenance phase.

The findings and recommendations of the research group from Lahore did not become available until shortly after this plan was

drawn up in August 1967. Even so, sufficient resources were foreseen in the plan to permit surveillance and containment activities of the type recommended.

By December 1968 major problems had become apparent. The government did not increase the budget but, in fact, decreased it by 30%—to 1 million rupees. The plan envisaged the use of local body vaccinators as part of the complement of personnel but they were responsible to their own union councils (administrative units each responsible for a population of about 10 000) and the councils, in turn, to the Ministry of Basic Democracy. As the WHO adviser was to report: "A number of vaccinators have been appointed under political pressure and many of them are recommended by influential persons and are engaged in other duties or private jobs." Likewise, vaccinators in the municipal areas were under an entirely different jurisdiction, and there was no coordination of their activities with those of the provincial or regional staff. The problems of programme direction were further complicated when supervisory staff indicated that they could not travel to the field because the government's travel allowance was too meagre to cover the cost of even the most austere board and lodging. Last but not least of the difficulties was that no provision had been made for the purchase from programme funds of freeze-dried vaccine from the government's quasi-independent Dhaka laboratory. Up to this time, liquid vaccine had been purchased by union councils with their own funds and no administrative mechanism existed to permit these funds to be diverted to the purchase of freeze-dried vaccine.

One by one, the problems were solved or partially solved by a variety of means. Because vaccine production at the Dhaka laboratory was found to be inadequate to supply more than East Pakistan, WHO provided freeze-dried vaccine which had been contributed by various donors, primarily the USSR. WHO agreed to provide funds to supplement the travel allowance of national supervisory staff to permit them to travel to the field. The Ministry of Basic Democracy was, with difficulty, persuaded to issue an order to the union councils directing local body vaccinators to work with the programme, an order which was subsequently ignored as often as it was respected. Eventually, the national government authorized additional funds to recruit the requisite staff.

Table 14.23. Pakistan: WHO support provided to the smallpox eradication programme, 1967–1978 (US\$)

<sup>a</sup> Excluding supplies of vaccine (about 70 million doses).

<sup>b</sup> WHO records reflect support given to both West Pakistan and East Pakistan (which became the Independent state of Bangladesh in December 1971). Approximately half of the total was provided to West Pakistan and these are the figures shown in the table.

The programme in the 16 districts began in June 1969, but outside these districts no effort was made to develop reporting or surveillance activities. Even in the 16 districts, the so-called "fire-fighting" and surveillance teams did little. Indeed, in Lahore, one of the principal urban centres, a surveillance programme was not established until May 1972.

In all, some 1600 government staff participated in the unnecessary mass vaccination campaign in the 2 regions. The campaign was completed at the end of May 1970. One million primary vaccinations and 22 million revaccinations were recorded in a population of 27 million persons. Between March and May, 313 000 persons in 546 localities were examined to determine the level of vaccinal immunity achieved. The survey revealed that only 3.7% of them had neither a vaccination scar nor the pockmarks of smallpox. Even making allowance for possible errors in the assessment, it was apparent that the residual number of susceptible individuals was small but, as the research group from Lahore had shown, the number of unprotected persons had not been large when the vaccination campaign began. The marginal improvement was confirmed by a study in a division in which the health services were the least adequate: before the campaign, 10.5% of the population were found to be unprotected; after its completion, 8% remained unprotected.

### One Programme Becomes Six, July 1970

On 1 July 1970, the administrative divisions of West Pakistan were abruptly changed by the government as part of the efforts to cope with increasing tensions in the relationships between East and West Pakistan. As has been mentioned above, the province of West Pakistan was divided into 4 independent provinces and 2 small, federally administered regions in the north of the country (Azad Kashmir and Gilgit) (Fig. 14.11). The populations of the provinces differed greatly in size: Punjab, 32.1 million; Sind, 11.9 million; North-west Frontier Province, 9.5 million; and Baluchistan, 1.6 million. The 16 districts in which the mass vaccination campaign had been conducted were all in Punjab Province, along with 3 additional districts. Early in the autumn of 1970, mass vaccination was completed in

Fig. 14.11. Pakistan: provinces (or federally administered areas) and districts in July 1970.

these 3 districts, during which an additional 200 000 primary vaccinations and 2.4 million revaccinations were reported to have been given. However, as shown in Fig. 14.12 and Table 14.24, the total of 25.6 million vacci-

<sup>a</sup> Mass vaccination campaign conducted during which 25.6 million vaccinations were performed.

nations performed in Punjab Province had little impact on the reported incidence of smallpox.

The failure of the campaign to have any apparent effect on the reported number of cases might be thought to reflect a better notification of cases, which masked the effect of the vaccination campaign. In fact, however, the surveillance teams functioned poorly and the notification system was not improved during this period.

Because of the subdivision of West Pakistan into 4 separate provinces and because each of the provinces was granted almost total autonomy in health matters, new provincial governments had to be persuaded of the need to undertake a smallpox eradication programme, to create some sort of organizational structure, to establish a budget and to recruit and/or assign personnel. In 3 of the provinces, no smallpox eradication activities had yet been undertaken. The national government and the national programme director had responsibility for the signing of agreements with WHO to permit advisers to be assigned and equipment to be provided, but had no authority over field activities except in the remote and sparsely populated Azad Kashmir and Gilgit.

The constraints on federal authority are illustrated by the frustration experienced in endeavouring to establish a vaccine production facility in the newly constructed national laboratories in the capital, Islamabad. In 1970 WHO offered to provide equipment for

vaccine production and consultant assistance to establish a facility, which, it was hoped, would produce vaccine for the whole of West Pakistan. The federal government insisted that this could be done only if the government of Punjab transferred funds to the federal government that had previously been used to finance the now defunct liquid vaccine production unit at Lahore. After prolonged negotiation, agreement was reached and WHO ordered and delivered the production equipment. Because of Punjab's later refusal to honour the agreement, the equipment was never used. Vaccine for the programme continued to be provided by WHO, initially from various donors but after 1973, from the Pasteur Institute in Iran, which donated large amounts of vaccine to WHO.

In an effort to establish a programme encompassing the entire country, an inter-provincial meeting was convened in December 1970 to seek the agreement of all provinces to undertake programmes. Two years had elapsed since the projected commencement of the programme in West Pakistan, but little had been achieved, except for mass vaccination in 19 districts. Meanwhile, the incidence of smallpox had remained virtually unchanged (Fig. 14.13). The lack of accomplishment after the expenditure of effort in districts with the most developed government and health structures and the greatest resources offered little encouragement for success at a national level.

Fig. 14.13. Pakistan: number of reported cases of smallpox, by month, 1967-1974.

#### The Fourth Year of the Programme, 1971

At the meeting in December 1970, representatives of each of the provinces of West Pakistan agreed to give high priority to smallpox eradication: to create the necessary administrative structure, to develop a reporting and surveillance system and to seek the necessary funds for a systematic mass vaccination campaign. WHO agreed to recruit 3 additional advisers so that one could be assigned to each province, the senior adviser continuing in his capacity as national counterpart as well as adviser to the programme in Punjab. Additional supplies and equipment were ordered by WHO and travel allowances were provided for senior supervisors in all provinces. Meanwhile, because title to the vehicles and other equipment provided by WHO remained with the Organization, some supplies from Punjab Province were transferred to other provinces, an otherwise impossible action in the case of government-owned supplies.

It was agreed that interprovincial meetings would be held twice a year to coordinate the 4 separate programmes. However, each programme developed more or less independently, employing different strategies and achieving varying degrees of success. All of them encountered difficult obstacles, in the first instance because of the diversion of resources due to the civil war in East Pakistan, and then as a result of the tension between India and Pakistan at that time. In December 1971, when East Pakistan became the independent state of Bangladesh, these difficulties abated and additional resources were made available to all programmes. Three additional WHO advisers were recruited, arriving between March and June 1971. They were assigned, respectively, to Sind, North-west Frontier Province and Baluchistan. However, little was done during that year in Baluchistan, or in Sind except in the city of Karachi.

In 1971, Punjab Province appeared to be the best candidate to achieve the early interruption of transmission. Because 60% of the

population of West Pakistan lived in that province, it was believed that the interruption of transmission there would provide an impetus to the other provinces. A programme had been in operation for 3 years, the mass vaccination campaign had been completed, and few susceptible persons remained. The reporting system had improved little since 1968, but with the vaccination campaign finished, smallpox staff found themselves with few responsibilities other than to develop a surveillance-containment programme. In May, 8 assistant superintendents of vaccination and 19 vaccinators were trained in surveillance activities and began working in 2 teams under the direction of the Provincial Smallpox Eradication Officer, Dr M. B. Khawaja, who was succeeded by Dr Mohammed Rafique. In the summer of 1971, all district health offices were ordered to send weekly telegrams to report the number of cases discovered during the week. With 1407 health units (172 hospitals, 893 dispensaries, 39 rural health centres and 303 maternal and child health centres) in which cases might be identified, it was reasonable to expect that the reporting of outbreaks would be quite complete if a system could be developed.

Because there were only 2 large teams engaged in search and containment in a province of 32 million people, and because telegraphic reports were then being received from less than half of the districts despite the provincial order, many outbreaks continued to be overlooked. More important, little was done in urban areas—the chief foci for the dissemination of smallpox. Programmes in the urban areas were the responsibility of the municipal corporations, each of which had its own health structure, and these, independent of provincial policies and supervision, continued to carry out traditional routine vaccination campaigns.

During 1971, the Punjab surveillance teams investigated 81 outbreaks, in which 561 cases had been reported; an additional 1475 cases were discovered. Although the total of 2036 cases was the same as that recorded in 1969, when the vaccination campaign began, the number of cases declined sharply in the latter half of the year, only 20–90 being reported monthly between July and November.

Meanwhile, in North-west Frontier Province, an energetic WHO adviser, Dr G. P. Marchenko, arrived in March 1971. With the help of an able provincial medical officer, Dr

Mohammed Ayaz Khan, the province launched a mass vaccination campaign in May in 4 of its most populous districts—Peshawar (the capital), Mardan, Hazara and Swat. In contrast to Punjab, case detection was specifically emphasized as an important component of activity. Numerous cases were discovered by the vaccination teams (Table 14.25; Fig. 14.14). By the end of the year, 2654 cases had been detected, most of which (2132) were in the 4 districts in which the campaign was being conducted. This was 5 times the number recorded during the preceding year. The

"epidemic" alarmed provincial authorities but stimulated political interest and support, which continued throughout the rest of the programme.

### Commencement of Country-wide Activities, 1972

During 1972, smallpox eradication programmes were introduced in Sind and Baluchistan Provinces and activities at last extended throughout most of the country. The provincial programmes progressed at different speeds and encountered such different problems that each is described separately. The remarkably successful programme in North-west Frontier Province is dealt with first. Transmission was interrupted only 2 years after the programme had begun, but the area was inundated by importations from the other 3 provinces for more than a year thereafter. Next to be discussed is the programme in Punjab, with its large population and attendant operational problems, and then the inadequately supported and poorly organized programmes in Sind and the sparsely populated Baluchistan. Table 14.26 shows the number of reported cases by year for each of the provinces during the period 1970-1975.

#### North-west Frontier Province

North-west Frontier Province extends from the foothills and mountains of the Himalayas along the border with Afghanistan to the plains of the Indus river in the east and south-east (Fig. 14.15). About three-quarters of the population are traditionally independent Pathans, some of whom at that time enjoyed semi-autonomy in federally administered tribal areas in the mountainous districts of Waziristan, Khyber, Kurram, Malakand and Mohmand. Extensive vaccination cam-

paigns had been conducted during the preceding years throughout the plains and foothills, as in Punjab, but in some sparsely settled mountainous and tribal areas variolation continued to be practised.

The house-to-house vaccination campaign, which began in May 1971 in 4 districts, was completed in June 1972. A staff of 350 persons vaccinated 3.6 million people (about 80% of the 4.4 million inhabitants of the area). Initially, the search for cases and the containment of outbreaks were limited to these 4 districts. In July 1972, vaccination campaigns were initiated in the districts lying in the Indus river plain (Kohat, Bannu and Dera Ismail Khan) and efforts were made to launch

1975	0	0	0	0	0	0

campaigns in the tribal agency districts. The latter were soon abandoned, however, when it was discovered that frequently only 5% or less of the population would accept vaccination. Data on the efficacy of the vaccination campaign are available from surveys conducted in 1973 in 5 districts. The results were, in general, comparable to those in Punjab (Table 14.27).

Simultaneously with the beginning of a vaccination campaign in the Indus river plain, case detection and outbreak activities were extended throughout the province. Six "fire-fighting" teams, each with a vehicle, were trained and assigned responsibility for designated districts to improve case notification and to detect and contain outbreaks. Meanwhile, in Peshawar, the capital, 20 teams of 2 persons each began a house-to-house search for cases. When cases were discovered, an 8-man team carried out containment vaccination. For the first time in Pakistan, the strategy which had been recommended 5 years earlier by the Pakistan Medical Research Centre team was finally to be implemented.

The number of cases steadily decreased during the late spring and throughout the summer—the seasonal low point in smallpox transmission—and from October to the end of December, only 100 cases were discovered, of which 98 were in Peshawar District. The outbreaks all occurred near Peshawar City, in small villages frequented by smugglers from the tribal areas. None of the outbreaks was large but containing them proved difficult because the villages were considered to be dangerous, especially at night, and the villagers often refused to provide information about cases. Additional impetus was given to the programme, however, when in November a new WHO adviser arrived—Dr Reinhard Lindner, who had played an important role in developing the surveillance-containment

strategy in Indonesia. Gradually, the problem in Peshawar came under control, and in April 1973 the last cases occurred in that district.

Meanwhile, cases began to be reported in January 1973 in the tribal areas of Kurram and Khyber, probably introduced from Peshawar. The teams were permitted to enter the area only with a military guard and only after assuring tribal leaders that they would not vaccinate them but would merely document the numbers of cases and deaths. In all, 101 cases were recorded in the outbreaks. Fortunately, smallpox transmission ceased spontaneously, probably in response to the traditional practice in villages of isolating cases and permitting only those previously infected with smallpox to care for the patients.

During the first 6 months of 1973, the only cases detected in the entire province apart from those in Peshawar and the Kurram-Khyber tribal area were 2 imported into Mardan from Punjab Province in January, and 2 in Swat notified in May following an importation from Karachi. By May, it appeared that transmission had been interrupted. The vaccination campaign was stopped and the vaccinators were assigned solely to a search for cases. A reward of 25 rupees (US\$2.50) was offered to anyone who detected a case. Numerous rumours were investigated but no cases were found. In October, the reward was doubled.

In November, however, importations began, primarily from Punjab but also from Sind and Baluchistan. Between November 1973 and September 1974, 35 outbreaks and 173 cases occurred. Of 34 outbreaks for which a specific source could be identified, all could be traced to Punjab, except 3 from Sind and 1 from Baluchistan. All but 3 of the cases were in the northern districts of Hazara (136 cases), Swat (26 cases), Dir (7 cases) and Mardan (1 case). The province's final outbreak of 3 cases occurred in the southern district of Dera Ismail Khan, the last on 7 August 1974. Subsequent extensive search and a reward which was progressively raised to 200 rupees, then to 500 rupees and finally to 1000 rupees failed to uncover further cases.

Only partial data are available regarding the age distribution and vaccination status of cases in the province (Table 14.28).

As in Afghanistan, only a small proportion of cases occurred among adults, of whom, however, one-third had scars indicating previous vaccination. Fifty-eight percent of the

cases occurred in children under 5 years of age, and although 10% were reported to have been vaccinated before onset, in some instances vaccination had been performed late in the incubation period during containment vaccination.

The achievements of the programme in North-west Frontier Province were notable. In April 1973, less than 2 years after the start of activities, transmission was interrupted, despite a health structure inferior to that of either Punjab or Sind Province, despite the greater difficulties of transport and communication and despite the existence of large population groups which refused vaccination. One might suppose that the authorities of other provinces would have found its programme and strategy instructive but, in fact, they openly doubted the reported results. In rancorous interprovincial meetings, they expressed scepticism and denounced the authorities of North-west Frontier Province for asserting that after April 1973 the only cases of smallpox that had occurred there had been imported from their provinces. Most adamant and vocal were representatives from Punjab Province.

#### *Punjab Province*

During 1972, Punjab Province strengthened its surveillance programme. Instead of 2 large surveillance groups, more surveillance teams of smaller size were created, each of which travelled extensively to improve reporting from the districts (Fig. 14.16) and to search for cases village by village. In all, 1495 cases were detected, 500 fewer than in 1971, when reporting was far less complete. Outbreaks were detected and contained reasonably quickly—73% being detected within a month of onset and 97% within 2 months.

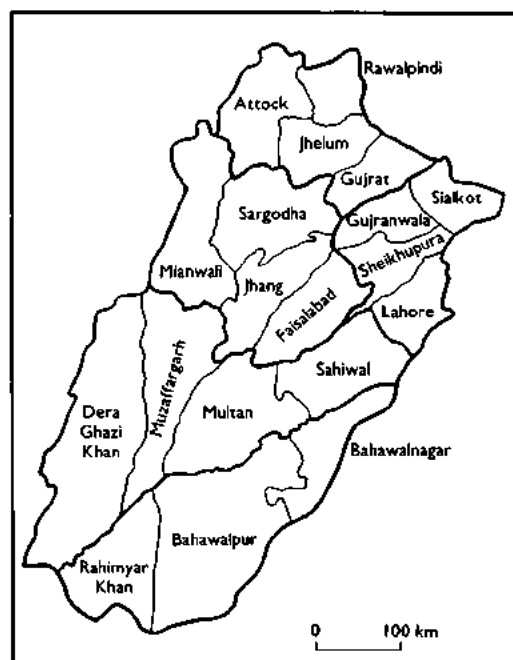

Fig. 14.16. Pakistan: districts of Punjab Province, 1973.

Little was done in urban areas, however, until May 1972, when special measures were taken to control smallpox in Lahore, the provincial capital. In the municipal corporation, 75 vaccinators were then working in 34 vaccination centres, only rarely leaving these centres to vaccinate people in the surrounding community or to detect and contain cases. It was agreed that a WHO adviser would be assigned to work in the corporation and, in May 1972, 6 sanitarians were trained in methods of case detection. One each was assigned to 4 sectors of the city and 2 were retained at headquarters to investigate cases brought to the infectious disease hospital.

Each of the 34 vaccination centres was designated a primary reporting unit, which would send reports weekly, and 51 of the 75 vaccinators were assigned to a house-to-house search for cases; a special containment team of 10 vaccinators was stationed at the provincial office. A report prepared in October documented 314 cases in 52 outbreaks in Lahore District, primarily in slum areas around the perimeter of the city. Almost one half (41.4%) of the cases were detected within 2 weeks of onset and 72% within 1 month. Only 4 outbreaks were traced to importations from other districts and these resulted in a mere 7 cases. However, numerous outbreaks, originating in Lahore, were identified during 1972 in other districts in the central and northern parts of the province. Indeed, between July and September, 37% of all cases in Punjab could be traced to Lahore. Cases in the city continued to occur primarily among unprotected persons, who had been found, in a 1969 survey, to constitute only 6.9% of the total population (Ali & Heiner, 1971). Although immigration may have increased the proportion of susceptible persons somewhat during the 3 succeeding years, a continuing vaccination campaign served to sustain vaccinal immunity. Attack rates among contacts in infected households substantiated the fact that those who had previously been vaccinated were at significantly less risk than the unvaccinated (Table 14.29).

The importance to the province of controlling smallpox in Lahore had long been pointed out and this was fully substantiated when an effective programme was finally begun. Coincidentally with a decrease in incidence in Lahore, the number of reported cases of smallpox in Punjab, as well as in neighbouring North-west Frontier Province, fell sharply during the summer of 1972 and

continued to decline during the autumn and winter months.

The programme was so successful that during March 1973, at the time of highest seasonal transmission, only 2 cases were detected in Lahore and only 8 in the entire province of Punjab. The Provincial Director of Health Services decided that the programme had succeeded and decentralized the surveillance operation. The Provincial Director of the Smallpox Programme was informed that he should undertake no further field travel and the WHO vehicle assigned to him was given to another medical officer. Each of the 5 divisional deputy directors of health services was assigned responsibility for one of the surveillance teams, and they in turn directed the teams to undertake other duties, primarily cholera vaccination. Surveillance in Lahore effectively ceased.

Through late October, the reported incidence of smallpox remained low; in fact, from 2 September to 20 October, no cases whatsoever were reported in Lahore District. It was the calm before the storm (Fig. 14.17). In late October smallpox outbreaks were again detected in Lahore, although investigations revealed that the city had, in fact, never been free of the disease. During December small-

pox spread widely through the city and cases began to appear in other districts and in North-west Frontier Province. By the end of December, 8 districts of Punjab had recorded outbreaks.

Despite the enormous resources and energies that had been devoted to the programme in Punjab, the situation had deteriorated to such an extent that conditions were not much better than they had been before the initiation of the mass vaccination campaign more than 5 years earlier. As at December 1973, the provincial smallpox eradication programme, such as it was, consisted of 4 wholly independent and uncoordinated components: (1) the Provincial Smallpox Eradication Officer with 8 assistant superintendents of vaccination and 14 surveillance agents; (2) 5 divisional surveillance teams under the direction of deputy directors of health services; (3) 19 independent district health offices, each with supervisors and vaccinators—some 1200 persons in all; (4) the municipal corporations, with their separate staffs.

It had been demonstrated beyond question in North-west Frontier Province that smallpox transmission could be interrupted even in difficult areas if the available resources were effectively managed. The problem in Punjab was to obtain an adequate political commitment, an appropriate strategy and a stability of leadership for long enough to permit this to be done.

Three events ultimately provided the necessary stimulus to a political commitment. The first was the recording in 1973 of 9258 cases of smallpox, the country's highest total since 1948. Although this could be attributed to more complete notification, the political authorities were alarmed and began both to query the performance of health officials and to make greater resources available. The second event was the interruption of transmission in Afghanistan in 1972, which caused some embarrassment in Pakistan. Afghanistan, considered to be a far less developed country, pointedly and repeatedly indicated to the Pakistani authorities that all its cases since mid-1972 had resulted from importations from Pakistan. The third incident was India's decision in the summer of 1973 to mobilize its vast resources of health manpower to undertake monthly village-by-village searches to detect and contain outbreaks throughout the country. Optimistically, the Indian government forecast that the interruption of transmission would occur

between January and June 1974. With Bangladesh and Nepal making excellent progress, it appeared that by late 1974 Pakistan might well be the last reservoir of smallpox in Asia.

Manpower in Punjab was not a problem but leadership and management were. A change occurred in February 1974 with the arrival of a new WHO adviser—Dr Omer Sulieman, the dynamic former director of the successful eradication programme in the Sudan. Within weeks, a moribund programme began to revive, and only 10 months later Punjab recorded its last case.

On his arrival in Lahore, Dr Sulieman reported on the situation: no plan or targets had been committed to paper; the concept of surveillance was accepted in principle but ignored in practice; officials continued to insist that vaccination targets should be met in all areas; there was no search for cases; containment was poor; and cooperation between different groups was so lacking that even data regarding cases were not forwarded to the provincial office.

The Secretary of Health extended full support and ordered district and municipal corporations to cooperate with the programme. A written document establishing guidelines and technical commitments was prepared and distributed; surveillance teams were reconstituted and trained; a reward of 10 rupees for each new outbreak reported was announced; and vaccinators were asked to search for cases among the groups of people they vaccinated. To intensify the search, population planning and malaria eradication staff were directed to undertake a house-to-house search for 1 week each month. When it was found that women were better received by the people and were more effective in searching for cases, 12 000 were employed between February and May; most of them were traditional birth attendants or municipal sweepers. In addition, during March, a special 2-day house-to-house search was conducted in Lahore by 50 000 schoolchildren and their teachers. They discovered 1800 persons with rash and fever of whom 13 were suffering from previously undetected smallpox.

Between February and May, substantial progress was made in the detection and containment of outbreaks but the smallpox incidence remained high. This was due, in part, to more complete reporting and, in part, to the high seasonal transmission. By June

1974, it was apparent that the cities of Lahore, Multan and Lyallpur (Faisalabad) were the key problems, accounting for the majority of cases and representing the source of infection of many rural outbreaks. In these cities, containment activities were strengthened, in line with the procedure then operating in India, by assigning a supervisor and 3 vaccinators to each outbreak to list and to vaccinate all residents and to stay in the area to vaccinate visitors until the outbreak was controlled. A vaccinator was also posted at each infected house until the last case had recovered. Efforts were also made to find and vaccinate all relatives, wherever they resided.

Whatever their instructions, some district health officers continued to rely on vaccination rather than surveillance and so, in June, routine vaccination was officially suspended and vaccinators were assigned solely to search and containment activities. To improve coordination, the Secretary of Health began to hold monthly meetings with all district health officers to emphasize his personal concern. In July, the health officers were relieved of other official duties in order to supervise a village-by-village search programme which covered one-third of the province's 23 692 villages each month. This programme was similar to that which had begun in India almost a year before.

With a declining number of cases and outbreaks—partly because of better control activities and partly because of the seasonal decline in smallpox incidence—it was possible to exercise better supervision in each remaining outbreak. Careful efforts were made to trace the source of cases and containment was tightened. Finally, on 16 October 1974, the last case of smallpox in Punjab, and in Pakistan as a whole, occurred in Multan City. The search continued, enhanced by the offer of a growing reward, but no further cases were found.

In Punjab, less than 10 months had elapsed since the introduction of the first well-coordinated province-wide programme of surveillance-containment and the occurrence of the last case. However, almost 6 years had passed since the beginning of the programme.

#### *Baluchistan Province*

Until 1972, little was achieved in the eradication programme in Baluchistan, the most sparsely populated and least developed of Pakistan's 4 provinces. It occupies 40% of

Pakistan's land area and is composed of desert and rolling hills with few roads. Only 10% of the land was arable, most of it being in the eastern districts, in which the population was concentrated (Fig. 14.18). Baluchistan was a new province, created in July 1970, and the government structure was only beginning to take shape. Communication and travel were difficult; the postal service was all but non-existent; and fewer than 100 physicians were employed there. Vaccinal immunity in Baluchistan was substantially lower than elsewhere in Pakistan, as was demonstrated by a scar survey performed in 1976 in 3 of the districts in which health services were the best (Table 14.30).

A mass vaccination campaign began in 1971 in the more populous north-eastern area of Quetta, Pishin and Zhob, employing some 30 vaccinators and some 20 support and supervisory staff. In fact, little was achieved, the numbers of recorded vaccinations for the province actually showing a decline, from 549 000 in 1970, to 422 000 in 1971.

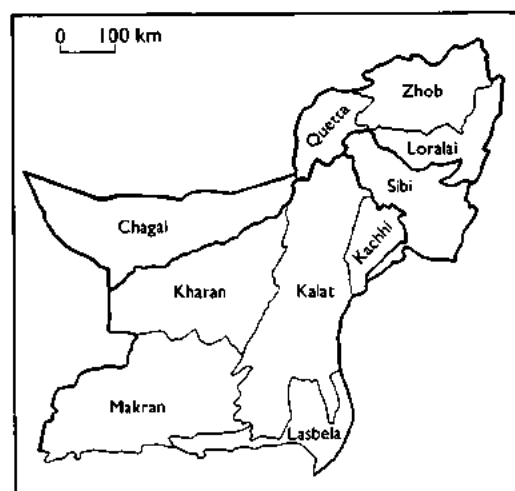

Fig. 14.18. Pakistan: districts of Baluchistan Province, 1973.

Table 14.30. Baluchistan: results of vaccination scar survey, in children 5 years of age and under, 1976

Quetta	6	78	0	29
Zhob	17	997	15	59
Total	42	1 794	17	50

In May 1971, a WHO adviser was assigned to the province, but the difficulties of maintaining even a few vehicles in operation in the field proved formidable. In the latter part of 1971 and in 1972, some outbreaks were investigated and vaccinations performed in and around Quetta, the capital, but little progress was made until the summer of 1972, when it was decided that a mass vaccination campaign was not feasible and the effort was abandoned. Surveillance agents were then posted to each district and 5 mobile teams, each composed of 4 persons, were constituted; 2 of these undertook a search for cases and 3 performed vaccinations in what were considered to be vulnerable areas. The number of reported cases increased from 80 in 1970 to 291 in 1971 and to 559 in 1972 (Table 14.31). Cases were reported from each of the 10 districts in 1972, but most of them (444) were in Quetta and the nearby town of Sibi, in which the mobile teams were working. In all, the teams themselves detected 486 (87%) of the cases.

The surveillance programme further improved following the arrival in February 1973 of an experienced WHO adviser, Dr P. R. Arbani, a national of Indonesia who had worked in the smallpox eradication programme in that country. By July, weekly reports of cases began to be received routinely from all districts. With improved training and increasing involvement of the few existing district and local health staff, cases were

Table 14.31. Baluchistan: number of reported cases of smallpox, by district, 1970-1974

District	1970	1971	1972	1973	1974
Chagai	0	1	2	2	0

Zhob	6	2	19	23	0
Total	80	291	559	801	202

detected more quickly and were better contained. During 1973, 165 outbreaks with 801 cases were documented. With the exception of 2 cases in Chagai, all cases were reported from the more populous north-eastern districts.

By 1974, the surveillance programme was functioning far more effectively. Only 40 outbreaks with 202 cases were discovered during that year, of which 27 were detected within 2 weeks of onset; 30 of the 40 outbreaks consisted of only 1 or 2 cases (Tables 14.32 and 14.33). The last 4 outbreaks (of 2, 18, 23 and 65 cases respectively) occurred in Baluchistan in the summer of 1974 and were associated with variolation in Kalat District. Although the outbreaks were quickly detected, many cases among variolated children were already late in the incubation period before the team arrived.

### Smallpox Transmission on Public Transport

Variola major was usually transmitted within the confines of a building, primarily in a household and sometimes in a hospital. Public transport was rarely implicated. This was because patients usually experienced a severe prodromal illness before developing rash and being able to transmit infection. Fortunately, few people travelled on public transport after first becoming ill but, if they did, infection could be disseminated rapidly and widely. One such episode occurred in Loralai District, Baluchistan, in July 1972.

On 21 July, a 4-year-old girl, accompanied by her mother, travelled 55 kilometres on a crowded bus to a medical clinic in Loralai town, returning home the same day. The girl had fallen ill with smallpox on 1 July and had become progressively worse, developing a confluent rash. She died only 2 days after the bus trip. On the bus, the girl and her mother rode in the front on one of 5 seats set aside for female passengers and separated by a partial partition.

Five persons, exposed on the bus, subsequently developed smallpox: the 60-year-old bus driver and 4 girls ranging from 3 to 8 years of age. Four additional persons, exposed at the clinic, also developed smallpox. As a result, outbreaks developed 2 weeks later in 12 different villages over a distance of 65 kilometres. Thirteen additional cases occurred before the outbreaks were contained. (WHO/SE/72.41, Suleimanov & Mandokhel.)

Table 14.32. Baluchistan: interval between onset of first case of smallpox and detection of outbreak, 1973-1974

1974	16	11	2	10	39 <sup>a</sup>

<sup>a</sup> Information not available for 1 outbreak.

Table 14.33 Baluchistan: number of cases of smallpox in outbreaks, 1973-1974

Year	1 case	2 cases	3-10 cases	> 10 cases
1973	76	24	52	13
1974	23	7	6	4

After April 1973, all cases and outbreaks occurred near Quetta, in which the isolation ward of the civil hospital served as the principal focus for the dissemination of infection. In addition to being the source of Afghanistan's final outbreak, mentioned earlier, the hospital was the focus of infection of 25 additional outbreaks over a 3-year period (including the last 4 outbreaks in Quetta), all of which were traced to patients who had contracted the infection there. Despite con-

tinuing efforts by provincial smallpox eradication staff to persuade the responsible hospital authorities to isolate patients and to vaccinate all persons admitted to the hospital, here, as at so many other hospitals, little was done until smallpox eradication staff were assigned to perform these duties.

Baluchistan recorded its last case on 30 August 1974. An extensive search was then organized throughout the vast, sparsely settled desert areas of its western provinces but no cases were found. Transmission had been successfully interrupted in less than 2 years after a surveillance programme had begun—and without benefit of a mass vaccination campaign. The costs were low. The total expenditure by the government over a 3-year period from mid-1971 to mid-1974 was 610 000 rupees (US\$61 500), or US\$0.24 per head of population.

Fewer than one half of the cases in Baluchistan were among children under 5 years of age; one-fifth were among persons aged 15 years and over (Table 14.34). The generally older age distribution of cases reflects the occurrence of smallpox in comparatively isolated population groups among whom, in contrast to the situation in Afghanistan, variolation had not been widely practised in recent years.

### The Last Outbreak in Baluchistan

Four weeks had elapsed without the reporting of a case in Baluchistan, when, on 1 August 1974, the assistant commissioner of a subdistrict reported to the district health officer in Kalat that he had heard rumours of smallpox in the area. A team immediately went to investigate and discovered cases in 4 villages (population 585) located at the top of a mountain, accessible only on foot. The first case had been exposed at Quetta's civil hospital in May and had become ill on returning home. On 4 June, a variolator was summoned; he took scabs from the patient and variolated the residents of the 4 villages. Between 4 June and 15 August, there were 108 cases and 9 deaths, as shown in the following table:

Age group (years)	Natural infection		Variolation	
	Number of cases	Number of deaths	Number of cases	Number of deaths
<1	0	0	3	2
1-4	2	0	19	0
5-14	3	0	26	0
≥15	11	2	44	5
Total	16	2	92	7

None of those infected had ever been vaccinated. Although the inhabitants of the 4 infected villages had a low level of vaccinal immunity, 90% of the people in surrounding villages were found to have been vaccinated.

### Sind Province

In Sind Province, which mainly comprises a flat alluvial plain, 40% of the population lived in urban areas, including the cosmopolitan city of Karachi (Fig. 14.19). It was comparable to Punjab in the extent of its health programmes and personnel and in the availability of transport and communication facilities. In all, Sind had 120 hospitals, 918 dispensaries, 103 rural health centres and subcentres, and 116 maternal and child health clinics. In 1972, vaccinal immunity was found by survey to be over 95% in Karachi, and although lower in the rural areas, generally speaking it was probably comparable to that in Punjab and much better than that in Baluchistan or in North-west Frontier Province.

Fig. 14.19. Pakistan: districts of Sind Province, 1973.

Except in Karachi, the smallpox eradication programme was effectively ignored until the autumn of 1972. Early in 1971, the Karachi city authorities consolidated into a single organization the vast numbers of vaccinators who had been employed by a variety of different administrative jurisdictions, to undertake systematic vaccination and a programme of case detection. Three, later 6, surveillance teams and 3 containment teams complemented this effort, which proved so successful that between July and September 1971 no smallpox cases were found in the city. A week-long, city-wide search in mid-November confirmed the absence of cases. Karachi, however, was Pakistan's largest city and principal seaport and numerous travellers from all over the country passed through it. Most of them were from other parts of Sind in which the smallpox incidence was probably higher than anywhere else in Pakistan. Importations led to a number of cases (369 in 1972, 335 in 1973 and 252 in 1974), and some outbreaks in other parts of Pakistan were traced to Karachi. However, smallpox in Karachi remained a minor problem in comparison with the situation in Lahore.

Provincial health authorities exhibited little interest in the programme until the autumn of 1972. The existing smallpox eradication staff of 724 persons, including 644 vaccinators (1 for every 23 000 persons) continued a routine vaccination campaign during which 3-4 million people were reported to be vaccinated annually. Reluctantly, the provincial authorities had agreed to the assignment of a WHO adviser, Dr M. Chamsa, who arrived in June 1971. Efforts had been made to mount a special vaccination campaign but lack of government support soon caused the attempt to be abandoned, and attention was focused on surveillance. With only limited resources available, this commenced in the autumn of 1972. Outbreaks were soon detected in every district—727 in all, with 3661 cases (Table 14.35)—4 times the number of cases reported during the previous year. Even so, weekly reports were not received from all districts, nor was an active search for cases begun until late in 1972.

By the autumn of 1972, national and WHO staff had become increasingly concerned about the inadequacy of the Sind programme and the lack of interest on the part of the health authorities. By that time, the smallpox

Table 14.35. Sind Province: number of reported cases of smallpox, by district, 1970-1975

District	1970	1971	1972	1973	1974	1975

Total	1 107	827	3 661	7 848	5982	0

incidence was declining rapidly both in Punjab and in North-west Frontier Province. The programme in Baluchistan was proceeding slowly, but since the population of the province amounted to only 1.9 million, it was of less concern. In Sind, which was much more densely populated, an effective programme was vital. Accordingly, in November 1972, WHO convened a special seminar in Karachi in which provincial officials from all

over Pakistan participated, together with smallpox eradication officers from other countries in the Eastern Mediterranean Region. The site had been deliberately selected in the hope of awakening the interest of senior officials in Sind. Henderson observed in his opening remarks:

"As for Sind, the considerable delay in initiating the programme and the many administrative problems encountered leave more yet to be done in the Province than in the other three ... I can say honestly to you that in no other previously or presently endemic region are so many engaged in smallpox eradication; in no other endemic region are health services, transport and communications so well developed nor the populations so willing to accept vaccination." (SE/72.9, Henderson.)

Despite the fact that the surveillance system in Sind had improved little, the total of recorded cases in 1972 rose to unprecedented levels. This event, coupled with the conference, served at last to stimulate the health authorities to undertake a more effective programme.

Following the conference, activities were reorganized. Additional surveillance teams

Plate 14.8. Participants in the training seminar in Karachi, Pakistan, in November 1972. Left to right, front row: Khin Mu Aye (WHO), A. J. Hajian (WHO), A. K. Tabibzadeh (WHO), A. W. Katpar (Pakistan), D. A. Henderson (WHO), E. Shafa (WHO), F. Jurji (Iraq); Back row: N. Mohammad (Afghanistan), A. M. Darmanger (Afghanistan), unidentified, M. A. Dardmal (Afghanistan), M. Salehi (Afghanistan), G. D. Suleimanov (WHO), V. V. Fedorov (WHO), unidentified.

were constituted for search and containment and soon the number of reported cases increased dramatically (Fig. 14.20), from 3661 in 1972 to 7848 in 1973. Even so, detection was greatly delayed and when outbreaks were found, containment was poorly executed. The problem was apparent from the observation that 43% of all outbreaks in 1972 and 24% in 1973 lasted more than 4 weeks (Table 14.36); 15% of all outbreaks in 1972 and 9% in 1973 had 11 or more cases (Table 14.37).

By the autumn of 1973, it was apparent that additional measures would be required. What-ever had been said about a change in strategy, district and local supervisory staff continued to be preoccupied with routine vaccination, undertaking case search and outbreak containment only with reluctance. Accordingly, in October 1973, activities were implemented that were similar to those which had been developed in India. To emphasize that the objective of the programme was to detect cases, vaccinators were redesignated "surveillance agents". Teams of 2-3 persons were scheduled to visit once a month all villages (usually 100-150) in 2-3 union council areas to detect and contain outbreaks. Activities

1974	1 272	639 (50)	552 (43)	81 (7)

were supervised on the spot by a district superintendent of vaccination and a district smallpox eradication medical officer. Several provincial teams assisted in districts with the greatest problems. In Karachi, staff of the family planning and malaria control programmes participated in the search for cases. To encourage participation, a reward of 5 rupees (US\$0.50) was offered to anyone finding a case. However, as a provincial surveillance officer observed, even this system of active search was poorly executed, the searchers devoting more time to obtaining the signatures of village leaders and teachers to prove they had been to the village than to searching for cases. The comparatively few special surveillance teams actually discovered more cases through questioning school-teachers and persons encountered during their travel.

The results were dramatic nevertheless. Cases were discovered more promptly and were better contained. In 1974, 50% of all outbreaks consisted of only a single case and only 43 out of 1272 (3%) lasted more than 4 weeks.

During the summer of 1974, the number of cases fell steeply, from 1100 in May to 300 in June and only 55 in August. This corresponded to the customary seasonal decline in incidence observed throughout Pakistan, but with the momentum of search and containment achieved during the winter months, the few remaining outbreaks were more effectively contained. Finally, on 28 September, the last case occurred in Sanghar District, just prior to the beginning of the seasonal increase in transmission. However, programme staff remained sufficiently sceptical of the

adequacy of surveillance that months were to elapse before they expressed confidence that transmission had in fact been interrupted.

Cases and deaths in Sind for the period 1972-1974 are shown in Table 14.38. Half of all the cases were in children under 5 years of age and only 8% were in individuals aged 15 and over, a marked contrast to the situation in Baluchistan. The overall recorded case-fatality of only 9% was unusually low for the subcontinent. Data from the city of Karachi (Table 14.39) suggest that this probably reflected incomplete notification of deaths in a province in which surveillance was notably poor.

As noted before, surveillance in Karachi had been consistently better than in the rest of Sind since 1971 and the cases which occurred during 1973-1974 had resulted primarily from importations from other parts of the province. Even when standardized for age, case-fatality rates were substantially greater than for the province as a whole, almost certainly reflecting more complete documentation of deaths rather than a difference in virus strains. A similar phenomenon had been observed in Indonesia, in which case-fatality rates were far higher in the city of Jakarta than in the surrounding West Java Province.

#### *Northern areas of Pakistan—Gilgit and Azad Kashmir*

In the federally administered, sparsely populated areas of Gilgit and Azad Kashmir, no special programmes were launched until 1974. Because the problems in the more populous areas of Pakistan were so formidable, neither national nor WHO staff considered it desirable to divert resources to these areas before then. It was hoped that in these northern areas, in which the population density was low, the transmission of smallpox might terminate spontaneously or be interrupted by control measures if cases were introduced. This proved to be the case. The population in Gilgit, estimated to be 450 000, lived in 5 different valleys in scattered hamlets and very small villages. A single rough road, open only 2 days a week, connected this area with the large urban centre of Rawalpindi, located in Punjab Province; as for connections by air, the single daily flight was often cancelled owing to bad weather. Between 13 000 and 100 000 vaccinations were recorded each year by hospital and dispensary staff. A reporting system was all but nonexistent. To assess the status of this area, an extensive search was conducted in the summer of 1976 but no evidence of recent cases of smallpox was discovered. Two unreported outbreaks were documented: 1 person in the eastern part of the region had developed smallpox and died in 1972, a week after returning from Karachi; and, in January 1971, 37 cases had occurred in the town of Gilgit, the largest urban centre in the region. Following the Gilgit outbreak, health staff, assisted by army personnel, had vaccinated nearly 150 000 persons. No surveys were done to document the levels of vaccinal immunity but it is doubtful that they were high.

Azad Kashmir, like Gilgit, is sparsely settled (population in 1975, 1 558 000), the people living in villages widely scattered over about 11 500 square kilometres of mostly hilly terrain. Many of the men travelled outside the area for work and, as a result, smallpox was introduced sporadically. In 1973, a special vaccination campaign was conducted by personnel of the 184 stationary health units, during which 1 381 294 persons were reported to have been vaccinated. Because of the lack of supervision or assessment of the programme, this figure was thought to be exaggerated. No information regarding cases was available before 1974,

Table 14.40. Dera Ghazi Khan, Bahawalnagar and Rahimyar Khan: results of variolation scar survey, by age group, 1976

Type of area	District	Number examined	Number variolated, by age group (years)					% of total examined
			0-2	3-4	5-14	≥ 15	Total

	Bahawalnagar	586	0	0	0	51	51	8.7

when an epidemiologist was assigned to the area. Between February and June, he documented the occurrence of 14 cases in 7 separate outbreaks, the last case occurring on 11 June 1974. No data were collected concerning the source of infection although it is assumed to have been the neighbouring province of Punjab. Extensive search in 1976 by special teams assisted by malaria control staff and local health personnel confirmed the absence of smallpox.

### Variolation in Pakistan

Variolation continued to be practised in isolated areas in Pakistan throughout the duration of the programme but it was far less extensive than in Afghanistan or Ethiopia and did not significantly affect progress. As has been noted above, the last cases in Baluchistan occurred in an isolated desert area of Kalat District, but evidence of recent variolation was also observed in the southern desert of Punjab and in mountainous tribal areas bordering Afghanistan.

Variolation in Punjab was limited to the Rahimyar Khan desert near the borders with Sind and Baluchistan; this practice persisted through 1973, and one unsuccessful attempt was detected as late as 1974. A survey in 3 districts in this desert area revealed extensive variolation in the past but no evidence of it in the preceding 4 years except in Rahimyar Khan (Table 14.40).

In the tribal areas of North-west Frontier Province, variolation by traditional variolators, as in Afghanistan, had been common. An investigation was conducted in 1976 in one such area in Mohmand Agency during which the inhabitants of 31 villages were checked for the scars of variolation and the pockmarks of smallpox (Table 14.41).

More than three-quarters of the population over 10 years of age had variolation scars but surprisingly few had pockmarks. Evidence of

Table 14.41. Mohmand Agency: results of survey of variolation scars and pockmarks of smallpox, by age group, January 1976

Age group (years)	Number examined	With variolation scars		Number with pockmarks

Total	856	474	55	51

<sup>a</sup> Males only.

variolation and/or pockmarks was seen only in children 3 years of age and older. This was supportive evidence that variolation had ceased, since it was usually performed when children were 1-2 years of age.

### CONCLUSIONS

Following the occurrence of the last case of smallpox in Pakistan in October 1974, extensive searches were repeatedly conducted throughout the 4 provinces and 2 federally administered regions to confirm the absence of smallpox; a reward of 100 rupees, later increased to 5000 rupees, was offered to anyone reporting an outbreak. Because of the programme's earlier record of poor performance and the inadequacy of surveillance, uncertainty existed until the end of the year as to whether transmission had actually been interrupted. Only after several months of continuing search during the period of high seasonal transmission did national and international staff begin to feel reassured.

The situation in Afghanistan was entirely different. Since 1970, continuing efforts had been made to strengthen reporting and all outbreaks had been carefully investigated,

their sources traced and the outbreaks contained. Surveillance was sufficiently extensive that when cases ceased to be detected, the Afghan staff were confident within a matter of weeks that natural transmission had ceased. However, since smallpox was still widely prevalent throughout Pakistan, there was a serious risk of its being reintroduced into Afghanistan and becoming re-established there. Indeed, transmission was interrupted more than 2 years earlier in Afghanistan than in Pakistan. Importations did occur but an effective surveillance programme quickly detected and contained the outbreaks.

In Afghanistan, there were few resources and only a rudimentary health infrastructure. Nevertheless, a highly effective programme rapidly took shape once a national commitment to the programme was made. In Pakistan, the resources were extensive, immunity was already high and a sound scientific basis for a programme had been elaborated. That Pakistan required so much longer to interrupt transmission reflects the difficulties of endeavouring to replace entrenched traditional doctrine—in this case, "100% vaccination"—with an alternative strategy that called for the detection and containment of outbreaks. Progress was unquestionably impeded by the attitude of some WHO advisers who, for so long, were not completely persuaded that this approach was correct. The delegation of authority and responsibility for health policy and programmes from national to provincial level further compounded the problem. Although national authorities attended the World Health Assembly, discussed global health policies and made commitments on behalf of Pakistan, provincial authorities bore the responsibility for deciding policy and

priorities within their own jurisdictions. Some supported an eradication programme while others exhibited little interest. National authorities could do no more than exhort and cajole. In consequence, a successful effort in North-west Frontier Province was jeopardized by the sudden collapse of the programme in Punjab, and both programmes were compromised by repeated importations of smallpox from Sind and Baluchistan, neither of which exhibited interest in smallpox eradication until late in the programme.

The question arises, in respect of Afghanistan, whether surveillance-containment measures alone might have succeeded, in view of the fact that transmission was interrupted so rapidly once these measures had been taken. Given the extent of variolation, it seems doubtful, in retrospect, that the staff could have dispensed with mass vaccination and the accompanying programme designed to educate village leaders and the villagers themselves about the dangers of variolation and the advantages of vaccination.

In 1968, the attainment of eradication in Afghanistan had been considered to represent the Intensified Programme's most difficult challenge. With the interruption of transmission there, senior WHO staff speculated anew as to which country or area might constitute the insuperable obstacle to global eradication. A few thought that it might be Ethiopia. Most, however, conjectured that it would be the populous country of India, which was generally believed to be the original home of smallpox and in which, perhaps, unique factors of climate, crowding, etc., permitted transmission to persist as in the case of cholera. In the next chapter we shall turn to the programme in India.

## INTRODUCTION

The Indian subcontinent has long been regarded as the probable place where smallpox originated—its traditional endemic home. It was a disease described in early Indian writings and enshrined both in Hindu religious belief and throughout the country in

temples to the smallpox goddess. Variola major, with a case-fatality rate of 20% or higher, was the only variety of smallpox found in India and, as recently as the 1950s, it is estimated to have killed more than a million persons annually. Many held the view that because of population density, or for other ill-defined socio-cultural or epidemiological

Fig. 15. 1. Bhutan, the states and union territories of India, and Nepal. Many of the most densely populated areas in the region are in the Gangetic plain. In India, Karnataka was known as Mysore until 1973; Arunachal Pradesh was the North East Frontier Agency until 1971; and Sikkim became a state in 1975. Bangladesh was East Pakistan until 1971.

reasons, the eradication of smallpox in India would ultimately prove impossible. This belief had its roots in the behaviour of cholera, which for centuries had been confined to the riverine areas of the Indian subcontinent. In the 1830s, cholera spread across the world in the first of seven global pandemics, only to disappear over time, except from the Ganges river plain (Fig. 15.1). Although cholera was a bacterial disease with wholly different epi-

demiological characteristics, many believed that there were unique, yet unrecognized features of this area which would doom a smallpox eradication effort as certainly as an effort to eliminate cholera.

There were other reasons for pessimism. In area, India was the world's seventh largest country but second only to China in size of population. Of the 1100 million people living in areas which had endemic smallpox in 1967,

Fig. 15.2. India: population density, by district, 1971.

513 million (47%) lived in India. The most densely populated zone was the Ganges river plain in the north (Fig. 15.2), some 2400 kilometres long and 240–320 kilometres wide. Sharing borders with India and epidemiologically related to it were the 2 small Himalayan mountain kingdoms of Nepal (population 10.8 million) and Bhutan (population, 987 000), and the Indian protectorate of Sikkim (population, 196 000). (Sikkim became an Indian state in 1975.)

A smallpox eradication campaign had begun in India in 1962 (Fig. 15.3) but, despite an intensive and costly effort, smallpox was still widely prevalent in 1967 and substantially underreported throughout the country. A pilot smallpox control programme had been launched in Nepal in 1962, but cases continued to be reported from the only 3 districts which reported at all. Little was known in 1967 about the situation in Bhutan and Sikkim.

In 1967, the meagre resources available to WHO precluded the provision of meaningful support to all endemic countries in Asia. A programme was already established in India, although functioning poorly, and India at that time requested international assistance only to permit the acquisition of equipment for vaccine production. Thus, WHO's assistance in Asia was directed to the less populous endemic countries—Afghanistan, Indonesia, Nepal and Pakistan (which then included East Pakistan, later to become Bangladesh). It was hoped that successful programmes in these countries would eventually permit the release of significant resources in support of the Indian national programme if required. A joint India-WHO team assessed the Indian

programme in 1967 and, subsequently, WHO staff from Headquarters and the Regional Office for South-East Asia in New Delhi held frequent meetings with Indian government staff. Until 1970, however, progress was slow. That year, a WHO-India agreement was signed which provided for WHO support for field activities. During the following 3 years considerable progress was made in the southern and western states but little in the northern, densely populated Ganges river plain. Meanwhile, country after country in Africa, South America, and Asia succeeded in interrupting smallpox transmission. By June 1973, only 5 endemic countries remained, of which 4 were adjoining countries in Asia (Bangladesh, India, Nepal and Pakistan) and the fifth was in Africa (Ethiopia).

In June 1973, Indian and WHO staff decided on an ambitious campaign to involve more than 100 000 local health staff throughout India in a village-by-village search for cases. Such searches would be completed in 7–10 days and would be undertaken monthly in heavily infected areas and less often in areas in which few or no cases were being reported. Outbreaks, when found, would be contained by local health staff assisted by state and district surveillance teams. With this strategy, it was hoped that transmission might be sharply curtailed by January 1974 and perhaps interrupted as early as June 1974. The problems proved far more formidable than had been foreseen. Although the original optimistic target was not met, transmission was interrupted in May 1975, less than 2 years after the special programme had begun—a considerable achievement in so vast a country.

In sheer magnitude and scope, in innovation and adaptation to adversity, in dedication and enthusiasm, in the degree of international cooperation and understanding, the Indian programme from September 1973 onwards was one of the finest endeavours of the global campaign. It is impossible to do full justice to this vast programme in a single chapter. Fortunately, a number of publications describe the overall programme, focusing primarily on its concluding phase. Two books, *The Eradication of Smallpox from India* (Basu et al., 1979) and *The Management of Smallpox Eradication in India* (Brilliant, 1985), are particularly valuable. Special issues of the *Indian journal of public health* (January–March 1978) and *The journal of communicable diseases* (August 1975) also provide important information.

Fig. 15.3. India: number of reported cases of smallpox, by year, 1950–1975.

This chapter includes an account of the closely related and ultimately well-executed Nepalese programme, of which there is no published description. It concludes with such information as is available regarding activities in Bhutan and Sikkim, which experienced only infrequent importations after 1966.

## INDIA

### Background

India's immense size and vast population, of whom more than 80% lived in rural areas, was but part of the challenge. In India, as well as in East and West Pakistan, there was an extraordinary movement of population from place to place for purposes of business and attendance at marriages and funerals. Numerous religious pilgrimages and gatherings attracted huge crowds, sometimes amounting to millions of people. Uncountable hundreds of thousands travelled throughout the country on 10 800 daily trains. The state transport system, including buses and other motor vehicles, alone carried some 10 million passengers (about 2% of the population) each day. Reflecting the extent of internal migration, the 1961 census showed that a third of the population was enumerated outside their places of birth that year; during succeeding years, mobility substantially increased. This was important in smallpox transmission. Often, persons who were exposed to or became ill with smallpox would journey long distances to return to their home villages, disseminating smallpox when they arrived and sometimes in the course of the journey.

Also unique to the Indian setting was a belief among Hindus that attributed smallpox to the wrath of a goddess, called *Sītālā* (*Shitala*) *mata* although known by a number of different names among India's 15 major language groups and 250 regional dialects. It was not surprising that a deity was associated with smallpox, considering the antiquity of the disease and the large numbers of people it afflicted, of whom 1 in 5 died. Its severity was illustrated by the fact that as late as the mid-1800s, 13% of all recorded deaths in Calcutta were due to smallpox, and 75% of blindness in India at that time was attributed to the disease (Rogers, 1944). Some persons resisted vaccination, fearing that it would anger the

goddess. Religious ceremonies in her honour were common at specially dedicated temples as well as in people's homes.

Finally, there were the complexities of the administrative structure. India, a parliamentary democracy, was divided into 21 states and 9 union territories. (In 1975, Sikkim became the 22nd state.) These were further subdivided into 393 districts and 5247 community development blocks (Table 15.1). Of the 575 721 villages enumerated in the census of 1971, approximately 319 000 had a population of less than 500; only 6333 had a population of more than 5000. There were only 4 cities with more than 2 million inhabitants: Calcutta (7 million), Bombay (6 million), Delhi (3.6 million), and Madras (3 million).

At the national level, responsibility for health programmes was shared by the Minister of Health, a political figure; the Secretary of Health, a non-technical administrative executive officer; and a technical Director-General of Health Services, who implemented health programmes. Substantive decisions required the collaborative understanding of all three. In each state the administrative structure replicated the national one. Although there was some variation in the type of organization from state to state, there were district health units in most, directed by a chief medical officer of health (or civil surgeon). In large states, several districts were grouped in divisions and, for each, there was a divisional medical officer. Districts were divided into basic health units termed primary health centres (corresponding usually to community development blocks), which attended to the health needs of 80 000–150 000 people living in 150–350 villages.

### Smallpox in India before 1962

Vaccination had first been performed in India in 1802 and an organized vaccination programme was begun in Bombay in 1827 (Rogers, 1944). By 1868, some type of vaccination programme had been established in all provinces, although little was done in most of the 560 independent princely states, in which about a third of the population resided. With increasing numbers of vaccinations, the numbers of registered deaths from smallpox declined between 1878 and 1937, despite a progressively improving system for the regis-

**Plate 15.1.** The goddess of smallpox has long been worshipped throughout the Indian subcontinent. She is usually portrayed as a woman riding on an ass, carrying a broom in one hand and a waterpot in her other arm. In northern India, she was known as Śītalā mata, śītalā meaning the cool one, and mata meaning mother. Though worshipped primarily by Hindus and Jains, in Nepal she was incorporated in the Buddhist pantheon as Ajima, the mother of Gautama Buddha. Offerings were made at temples dedicated to her and to images in the home; annual festivals were held on her feast day. Beliefs and practices differed from place to place and the goddess was variously considered to have powers to prevent or cure the disease as well as to inflict it.

<sup>a</sup> From Rogers (1944).

<sup>b</sup> United Nations (1985) estimate for 1967.

tration of deaths and a growing population (Table 15.2). Data comparable to those provided by Rogers could not be obtained for the period 1937–1961, but data for 1962–1971 are available—1962 being the year in which India commenced a special national smallpox eradication programme (see below). It is not known how complete the registration of deaths may have been at different times.

However, studies conducted during the early 1970s showed that even then, the number of reported cases of, and presumably deaths from, smallpox represented less than 5% of the cases and deaths that had actually occurred.

Vaccination programmes were gradually extended throughout most of the country and, following India's independence in 1947,

Fig. 15.4. India: pilot project districts for the National Smallpox Eradication Programme (NSEP), 1960–1961; state programmes assessed in 1967; and municipal areas assessed, 1963–1964.

to the remaining princely states. Thermolabile liquid vaccine was the only vaccine available and many of the vaccinations performed must have been unsuccessful. This vaccine was produced in 14 laboratories in 11 different states. As in Pakistan, vaccinators who were recruited and hired by the local administrative organization and termed "local body vaccinators" performed the vaccinations. The programme of vaccination provided only partial control of smallpox, but because vaccination was widely available and variolation was forbidden by law, the latter practice ceased and, by the late 1950s, was no longer a problem in India.

### India's National Smallpox Eradication Programme, 1962

In June 1959, one month after the decision of the Twelfth World Health Assembly to undertake a global eradication programme, an Expert Committee of the Indian Council of Medical Research recommended that a National Smallpox Eradication Programme should be established. The vaccination campaign that resulted was of heroic dimensions and, although failing in its goal to eradicate smallpox, it served to extend vaccination to all but the most isolated villages and created an army of workers and a momentum which provided a foundation for the subsequently successful eradication effort.

Pilot projects were first developed in one district per state to work out methodology and to develop estimates of costs and personnel requirements (Fig. 15.4). The projects began in 1960 and concluded in March 1961 (India, Ministry of Health and Family Planning, 1966).

The essence of the strategy called for a specially recruited team to move systematically from house to house and from village to village throughout a district in an effort to vaccinate or revaccinate not less than 80% of the population. With this proportion vaccinated, it was expected that a sufficient number of persons would be immune so that smallpox transmission would terminate spontaneously. The vaccination team was preceded by enumerators, who listed in a large multi-page register the name of each person along with his or her address, age, sex and previous history of vaccination or of smallpox. One register was compiled for each village or defined area in a city and was intended

to be used during the subsequent 20 years. After enumeration had been completed, the register was given to the vaccination team, which then endeavoured to vaccinate those who were listed. The register was next given to an inspector, who was to check each vaccinee to ensure that vaccination had been successful. Subsequently, local health unit vaccinators (1 for every 50 000–70 000 persons) were assigned responsibility to vaccinate those missed in the mass campaign ("mopping-up vaccination"), to maintain the registers, to revaccinate everyone every 5 years and to vaccinate contacts when cases were discovered. Performance in the pilot projects was poor. In a target population of 23 million, only 12 million (52%) were vaccinated. No evaluation of the programme was conducted nor was smallpox incidence monitored. Nevertheless, as happens only too frequently, the pilot projects were followed almost immediately by the introduction of a national programme.

The USSR offered freeze-dried vaccine, which was largely but not entirely intended to replace the thermolabile liquid vaccine; the United States Agency for International Development made a grant of rupees equivalent to US\$2 million; and UNICEF pledged equipment for vaccine production. Eventually, the USSR provided 650 million doses of vaccine and the USA, between 1961 and 1967, contributed the rupee equivalent of US\$23 million, which had been generated by the sale of foodstuffs provided to India (termed Public Law 480 funds).

Since health programmes in India are constitutionally a state responsibility, the principal administrative direction of the smallpox eradication programme was delegated to the states. Only 2 professional staff provided coordination at the national level. However, because smallpox was considered a national priority, the programme was "centrally sponsored"; the states were reimbursed by the central government for all non-recurring expenditures and for 75% of recurring costs.

The government created 152 units, each of which was expected to vaccinate about 3 million persons in an "attack phase" lasting 2–3 years. Each unit consisted of a supervising officer (usually a physician), a paramedical assistant, 60 vaccinators, 12 inspectors, 12 enumerators and 2 health educators. Each unit was assigned 3 vehicles. In all, more than 13 000 persons were employed, most of whom

### Recommendations for Primary Vaccination in Early Childhood, 1963

The programme's recommendations for primary vaccination were taken from a publication of the British Ministry of Health and distributed in a circular to all administrative staff in 1963. It stated that primary vaccination "should be carried out some time before the age of two years, preferably during the second year" and listed as specific contraindications: "failure to thrive, exposure to infectious disease, septic skin conditions, infantile eczema and other allergic conditions, hypogammaglobulinaemia and corticosteroid treatment" (India, Ministry of Health and Family Planning, 1966). Although perhaps appropriate for the United Kingdom, where smallpox cases were only occasionally imported, the recommendations were inappropriate for India, where many children were exposed to smallpox from birth, where the risks associated with vaccinating most of those with the listed contraindications were much less than the risk of death due to smallpox, and where most vaccinations were performed by scarcely literate vaccinators who could not be expected to recognize many of the conditions noted. Indeed, if all the contraindications had been carefully observed in India, few children would have been vaccinated. Sensibly, the recommendations were largely ignored by most vaccinators, although some did not vaccinate children who were ill with fever or had skin infections. Throughout India, 3 months of age was generally respected as the lower age limit for vaccination. By 1970, a more realistic and appropriate policy had evolved. It called for vaccination from the time of birth and recognized no contraindications except one: vaccinators were instructed not to vaccinate seriously ill persons who might be expected to die over the succeeding day or two and whose death might thus erroneously be attributed to vaccination.

were newly hired and trained. The programmes were launched in 1962 and 1963.

Between 1962 and 1966, 440 million vaccinations were reported to have been performed. It was an impressive number but it did not signify that this many persons had been rendered immune. The first indication of difficulties was observed in New Delhi in the winter of 1963 (Gelfand, 1966). Between December 1962 and May 1963, 346 cases of smallpox occurred in an area in which the number of vaccinations performed was equivalent to more than 80% of the population. Sample surveys conducted in 18 representative areas revealed that, in fact, vaccinations had been given to only 63% of the population and that, of these, 86% had been successful. It was therefore concluded that only 54% of the population had been successfully vaccinated. This discrepancy between the number of vaccinations reported and the number of people actually rendered immune was attributed to a falsification of records and the repeated vaccination of readily accessible groups, particularly school-children. The government was disturbed by these findings and asked India's National Institute of Communicable Diseases to under-

take similar surveys in other states. Five were subsequently conducted in districts which reported that the number of vaccinations performed was equivalent to 80% or more of the population. In operational terms, this meant that the mass campaign "attack phase" had been completed or was about to be completed and the "maintenance phase" was due to begin; during the latter phase the established health services would assume the responsibility for sustaining levels of vaccinal immunity and for controlling outbreaks.

The findings of the National Institute's teams were not encouraging (Gelfand, 1966). The family registers—printed sheets sewn together in a large book—were supposed to include the name of each individual in a defined area and to provide a permanent record of vaccination status. Field assessment showed that many registers had already been lost or were so worn as to be unusable; many names had been omitted; and the clerical task of keeping the registers up to date was overwhelming. It was found, for example, that some individuals who had died as long as a year before were recorded as having just been successfully revaccinated. However in-

<sup>a</sup> No cases were reported during this period in the union territory of Andaman and Nicobar Islands.<sup>b</sup> Part of Assam.<sup>c</sup> Part of Punjab.

effective the family registers may have been, their use continued in many areas until the late 1960s.

The proportion of the population found to have been successfully vaccinated was less than the reported 80% in all districts, ranging from 54% to 73%. Substantially lower levels of vaccination coverage were found in urban districts than in rural areas. Although the numbers reported to have been vaccinated were probably somewhat inflated, the more basic problem was similar to that observed in New Delhi: the most accessible individuals—schoolchildren, for example—were being vaccinated as often as every 6 months, while pre-school children and persons in the lowest socio-economic groups, among whom smallpox was most prevalent, were not being vaccinated at all.

In areas which had entered the maintenance phase of the programme, the National Institute's teams evaluated performance by examining children aged 3–12 months for the presence of a vaccination scar. After the mass campaign, all children on reaching 3 months of age were supposed to be vaccinated by staff assigned to the local primary health centre. In one district, 88% of children 3–12 months old had vaccination scars, but in the remaining districts the corresponding proportions were, respectively, 2%, 9%, 23% and 38%. The National Institute's teams investigated reported cases of smallpox in the maintenance phase areas and in each district they found many other cases which had not been detected.

In view of the fact that the districts evaluated were among the few which had reported that they had achieved the target of 80% coverage, it was apparent that the programme had fallen far short of expectations. An internal document issued by the United States Agency for International Development in November 1964, justifying the programme's continued use of United States rupee funds, stated prophetically: "Eradication of smallpox in India ... is at least 10 years hence ..."

Despite the extensive vaccination programmes, 30 000–40 000 cases of smallpox were reported each year during 1964–1966 (Table 15.3). Because millions had been rendered immune through vaccination, a decrease in the true incidence of the disease is assumed to have occurred, although such a decrease might have been masked by a more complete notification of cases. However, no

specific measures had been taken to improve the reporting system and little is known about its efficacy at this time beyond the recognition that only a small proportion of cases was officially recorded.

Serious deficiencies extended throughout the reporting network at each level responsible for data collection and transmission. In villages, cases of smallpox, as well as of plague and cholera, were supposed to be reported to the primary health centre by the village headman in most states or, in some, by the village watchman (*chowkidar*)—a poorly paid, sometimes illiterate employee of the village council. Some villages submitted reports but many did not. Health workers, assigned to primary health centres, paid little attention to the reporting of smallpox.

An additional problem was that villagers sometimes deliberately hid cases to avoid vaccination, to which they objected for religious reasons or because they feared the painful, infected lesions which so often resulted from the use of the rotary lancet. Some persons who had contracted the disease concealed themselves to avoid being taken forcibly to congested and understaffed hospitals. The cases that came to the attention of primary health centre personnel and district officials were frequently not reported by them to higher authorities because they were afraid of being punished by their supervisors. Many supervisory staff acted on the premise that the occurrence of cases in an area was *prima facie* evidence that the health staff had done an inadequate job of vaccinating the population and so deserved punishment.

At that time, the Central Bureau for Health Intelligence, the national statistical office, simply recorded data, showing little interest in whether the districts and states reported at all. Even the simple task of recording data was confounded by a system, unique to India, which required each district to report each week the number of cases detected according to the week of onset of the cases. This differed from the practice in other countries, in which a weekly report was compiled giving the number of cases of smallpox *detected* that week, irrespective of the date of onset. Thus, instead of receiving and recording one number for each of India's 393 districts, the Central Bureau received new reports of cases for each district extending back weeks or even months. All numbers were entered in a great ledger, past numbers corrected and new

### Vaccination Using the Rotary Lancet

Until the bifurcated needle began to be used in 1970, vaccination was an elaborate and time-consuming ritual. Each vaccinator had a helper who carried a vaccination bag, and the pair proceeded from house to house to identify individuals to be vaccinated. When a candidate was found, the helper unpacked the bag and the following routine, prescribed by the Directorate of Health Services, was followed (India, Ministry of Health and Family Planning, 1966):

1. Check your kit bag to make sure that all the articles are there.
2. Perform vaccinations in a shady place to prevent exposure of the lymph to the sun.
3. Before vaccinating a person, wash your hands thoroughly with plain soap and water.
4. Sterilize both the scoop end and the toothed end of the rotary lancet in water brought to the boil beforehand and kept boiling. Hold the middle of the lancet with your thumb and index finger and dip the two ends in boiling water alternately for a minute each. If quick work is required, hold the two ends of the rotary lancet alternately over a naked flame. After sterilizing the lancet, keep it on a special wooden stand, taking care to see that the two sterilized ends do not come into contact with any other object.
5. Scrub the site chosen for vaccination thoroughly with plain soap and water. Wipe it dry with a sterile swab.
6. Take the vaccine tube from the ice container, unscrew its cap, take the lymph on the scoop end of the rotary lancet, recover the tube and put it aside on a special holder. Place the lymph on the required number of spots, on the outer surface of the middle third of the left upper arm for primary vaccinations, and on the front surface of the left forearm for revaccinations. Place the toothed end of the lancet on the skin through the drop of lymph. Rotate the lancet with gentle and even pressure so as to produce a light circular cut without drawing blood. After making the insertion, rub in the lymph into the scarified area with the scoop end of the lancet. Detain the person for 15 minutes so that the lymph may have time to get absorbed into the skin.

After one or several vaccinations had been performed at a house, the bag was repacked by the helper, and the vaccinator and helper proceeded to the next house.

Vaccinators who failed to permit the lancet to cool sufficiently or who were too vigorous in pressing it into the skin inflicted painful lesions. Because the lancets were often contaminated, the vaccination lesions frequently became septic. The scars which remained sometimes resulted from the growth of vaccinia virus but sometimes were caused by bacterial infection alone. Not surprisingly, many vaccinators were offered money *not* to vaccinate.

Given the routine and the need to record the name of each vaccinee in a large register, it was unusual for a vaccinator to perform more than 25 vaccinations a day. When the bifurcated needle became available, the procedure was greatly simplified and both the special bags and the helpers gradually disappeared. However, the pace of vaccination, by then well ingrained, did not substantially increase.

totals compiled. Similar procedures were followed by district and state statistical offices. However, many of these offices did not forward reports of cases which had occurred several weeks or months previously, considering them not to be of current interest.

The National Smallpox Eradication Programme Advisory Committee held a meeting in November 1965 to decide what should be done when, in March 1966, the attack

phase—the mass vaccination campaign—was scheduled to be completed and the programme throughout the country would enter its maintenance phase (India, Ministry of Health and Family Planning, 1966). The Director of the National Smallpox Eradication Programme, Dr K. M. Lal, expressed optimism that there would be a “further steep fall” in incidence in 1966–1967 but was concerned about the large number of persons who still remained unvaccinated. Because

independent assessments had shown that equating the numbers of recorded vaccinations with the numbers of persons successfully vaccinated was erroneous, it had been decided that a target of 100% vaccination coverage was necessary (a strategy endorsed by a WHO Expert Committee on Smallpox (1964) at Dr Lal's suggestion). Dr Lal doubted that a satisfactory maintenance vaccination programme could be conducted by the existing primary health centre staff, malaria workers, midwives and others. The 1963-1964 assessment had shown this. He favoured a plan which had been suggested to and approved by the Advisory Committee in 1963, whereby 1 smallpox vaccinator would be provided for every 10 000-15 000 persons in rural areas and for every 20 000 persons in urban areas. Such a scheme would be costly and, by any standard, would involve a generous deployment of manpower. Assuming that a vaccinator worked 200 days a year, he could theoretically vaccinate the entire population in a rural area during the space of a year by performing as few as 50-75 vaccinations a day.

Dr Lal and many members of the Advisory Committee were reluctant to end the attack phase with its mass vaccination units until cases had ceased to occur in a district. Various members proposed intervals of up to 3 years as the desirable time for an area to be smallpox-free before it entered the maintenance phase and vaccination was turned

over to basic health staff or local body vaccinators. A special subcommittee was appointed to explore the question further. However, budgetary considerations intruded. The government was forced to decrease expenditure, and the attack phase programme, with its 152 mass vaccination units, was terminated. Special vaccinators for smallpox continued their work in most areas, but in a few, a handful of poorly trained and poorly supervised basic health workers were expected to add vaccination to other tasks.

Meanwhile, vaccine production institutes at Patwadangar, Belgaum, Guindy (Madras) and Hyderabad struggled unsuccessfully to produce the large quantities of freeze-dried vaccine required. By 1966-1967, they were producing only 1.4 million vials (enough to vaccinate about 20 million people). The USSR continued to provide approximately 500 000 vials each month, but even this was not enough. Emergency requests to other governments were regularly channelled through WHO, and several million additional doses were received from the Netherlands, Switzerland and the United Kingdom, but none of these sources could supply substantial quantities since none had laboratories equipped for the large-scale production required. Accordingly, the thermolabile, questionably potent, liquid vaccine continued to be used in a number of states since it was felt that unsatisfactory vaccine was better than no vaccine at all.

Table 15.4. India: numbers of reported vaccinations, percentages relative to population, and numbers of reported cases of and deaths from smallpox, 1962-1976

Year	Primary vaccinations		Total vaccinations		Reported number of cases of smallpox	Reported number of deaths from smallpox
	Number	% relative to population <sup>a</sup>	Number	% relative to population <sup>a</sup>

1969	22 700 000	4.3	76 870 000	14.6	19 281	4 156
1970	23 060 000	4.3	77 110 000	14.4	12 773	2 240
1971	24 190 000	4.4	91 680 000	16.7	16 190	2 706
1972	26 950 000	4.8	112 730 000	19.6	27 407	5 457
1973	24 840 000	4.4	112 340 000	19.8	88 114	15 434
1974	24 180 000	4.2	123 430 000	21.3	180 003	31 262
1975	19 025 474	3.2	86 718 634	14.6	1 436	176
1976	16 745 086	2.8	66 854 231	11.1	0	0

<sup>a</sup> The percentages provide an index of vaccination activity and are derived by dividing the reported total number of vaccinations performed by the estimated total population (from Basu et al., 1979). The figures do not provide a measure of the proportion of the population newly immunized or whose immunity was boosted. Vaccination was sometimes unsuccessful and some individuals were vaccinated two or more times in a year. Moreover, the reported total numbers of vaccinations performed were sometimes inflated.

The Herculean effort to eradicate smallpox through mass vaccination, launched so enthusiastically in 1962, had all but come to a halt by the time the Nineteenth World Health Assembly, in May 1966, decided to embark on the Intensified Smallpox Eradication Programme. The Indian delegate to the Health Assembly, commenting on the new initiative, pointed out that India would need 180 million doses of vaccine annually, of which it would never be able to produce more than 60 million doses, and expressed the hope that WHO could meet the projected deficit. He cautioned the delegates that unless good basic health services were developed "it would be very difficult indeed to maintain the immunological status temporarily reached" in a mass campaign (World Health Organization, 1966c).

In December 1966, Henderson, who had recently been appointed Chief of the newly constituted Smallpox Eradication unit at WHO Headquarters, arrived in New Delhi to participate in his first intercountry smallpox eradication seminar, attended by representatives from countries in WHO's South-East Asia Region. It was not an auspicious beginning, as India, which then accounted for one-third of the world's cases, announced at the seminar that it had terminated its attack phase and had reverted to a programme of maintenance vaccination.

### The Intensified Smallpox Eradication Programme Begins, 1967

The advent of the Intensified Programme in India found a discouraged staff. Dr Lal, the director of the National Smallpox Eradication Programme since 1962, retired and, because the attack phase had been terminated, was not replaced. This left at the national level only one medical officer, Dr Mahendra Singh, a Deputy Assistant Director-General of Health Services. Although he was overwhelmed by the tasks of giving some sort of direction to the remaining smallpox control activities and of providing the necessary reports to Parliament among many other duties—Dr Singh tried valiantly to stimulate the host of vaccinators distributed across India. He dispatched numerous cables and letters asking state health directors to take action to control epidemics reported officially to him or, as often, through the press. Vaccination targets were established for each

state and those who failed to meet their goals were given forceful reminders. The number of reported vaccinations diminished, however, from 139 million in 1963 and 130 million in 1964 to 96 million in 1967 (Table 15.4). Vaccine distribution was also Dr Singh's responsibility, and a continuing problem because reserves were few and requests to replenish vaccine stocks in state and district offices were often not forthcoming until supplies had been exhausted. Government regulations required that Dr Singh should travel by train or bus, often a 1- or 2-day trip to reach distant and populous state capitals. In each state, there was only one official responsible for smallpox, and he was usually assigned responsibility for one or more additional programmes. The smallpox eradication programme and its still extensive complement of vaccinators laboured under a severe shortage of senior, responsible staff.

### Assessment of the Programme in India, October 1967

In 1967, smallpox incidence rose dramatically, eventually reaching a total of 84 902 cases, more than had been reported in any year since 1958. Concerned by this turn of events, the Indian government agreed that a joint India-WHO assessment team should

WHO/C. FRUCHT, c. 1974

**Plate 15.2.** Medical officers at a primary health centre in Maharashtra State. Right: Mahendra K. Singh (b. 1928), a Deputy Assistant Director-General of Health Services, who was the only medical officer at the central level in India's National Smallpox Eradication Programme from 1966 to 1972 and sustained the momentum of the work until additional senior Indian and WHO staff could be assigned. He continued with the programme until the eradication of smallpox in India had been certified in 1977 and was later appointed Director of the Central Bureau of Health Intelligence.

appraise the situation and suggest how it might be rectified. The team's operations were planned and organized by Dr Jacobus Keja, the adviser on smallpox eradication in WHO's South-East Asia Region, and by Dr Singh. In India, an assessment such as this, in which WHO staff travelled to the field, was an uncommon event at that time. Most WHO advisers remained in New Delhi or occasionally visited the more populous state capitals, in which hotels were plentiful. When preparations were being made for the trip, it was discovered that the regional office had in its stores none of the commonly used Indian bedrolls that were needed when travellers stopped at government rest-houses.

The assessment team, comprising 8 senior national health officers and 8 WHO staff and consultants, spent 6 weeks in the field, from 8 October to 19 November. They visited Maharashtra and Uttar Pradesh, two states experiencing epidemic smallpox in 1967, as well as Punjab in the north-west, a state with moderate incidence, and the southern state of Tamil Nadu. The last of these states was of particular interest because of the very few cases reported (263 in 1967) among its population of nearly 40 million.

The observations made by the team are telling, as they provide an overview of the status of smallpox and of the programme in 1967. The team concluded that the programme "is still far from achieving its objective of smallpox eradication in most areas and ... in fact, a very considerable epidemic potential exists in India at the present time." The conclusions of its report are paraphrased below:

#### *Supervision and direction*

● The functions and responsibilities of the National Smallpox Eradication Programme from the central level to the periphery are fragmented

among a variety of independent and semi-independent organizations. There is lack of clarity and definition of responsibilities and objectives at all administrative levels.

● The central directorate is inadequately staffed and has no effective mechanism for exercising clear guidance and direction of the programmes at state and local level. Its functions are limited to the collection from the states of inadequate data regarding smallpox incidence and the number of vaccinations performed, the distribution of imported freeze-dried vaccine, the occasional organization of meetings of state and local programme directors, the distribution of some health education material and liaison with international organizations.

● The states exhibit a great variation in organizational structure. In many, responsibility for the programme is given to a senior officer burdened with many additional responsibilities. With few exceptions, the state directorates act merely as channels for funding, the transmission of instructions and the receipt of periodic reports from the districts.

● In the districts, the district health officer has overall responsibility for the programme as one of many responsibilities. Although as many as 3 paramedical personnel act as assistants, field visits are infrequent, supervision is poor, morale is low, interest in the programme is fading and vaccine is improperly handled and stored. Vaccinators are superintended partly by local administrative bodies and municipal boards and partly by the district staff.

#### *Programme execution*

● Legislation regarding compulsory vaccination varies widely. In some states both primary vaccination and revaccination are required, while in others vaccination is not compulsory. The laws governing enforcement involve cumbersome procedures, and fines are minimal and rarely imposed.

● The plan calls for the vaccination of all newborn infants and other individuals not

Table 15.5. India: vaccinator productivity and salary costs per vaccination performed, 1967

	Number of blocks studied	Number of vaccinations performed per vaccinator per day (range)	Cost per vaccination <sup>a</sup> in rupees (range)
State:			
Maharashtra	10	6.3 (0.5-11.3)	2.42 (13.9-0.48)
Punjab	8	5.7 (0.1-12.7)	3.17 (13.2-0.42)
Tamil Nadu	11	24.5 (6.4-51.6)	0.49 (1.04-0.16)
Uttar Pradesh	19	11.4 (3.1-37.2)	0.94 (8.71-0.20)
Municipality:			
Bombay		14.3	0.47
Madras		8.5	b

<sup>a</sup> Salary costs only—i.e., not including costs of vaccine, supervision, supplies or transport. (In 1967, 1 rupee was equivalent to US\$0.13.)

<sup>b</sup> ... = data not available.

previously vaccinated and the revaccination of everyone every 3 years; it also requires an assessment of "takes" among all primary vaccinees and 50% of revaccinees, as well as entry in the family registers of actions taken. The team concludes that none of the targets is being reached and that records are being falsified in most areas visited.

- The number of *vaccinators* is high (ranging from 1 for every 26 000 persons in Maharashtra to 1 for every 31 000 in Uttar Pradesh) but productivity is low [Table 15.5]. The mean number of vaccinations performed per day ranges from 5.7 in Punjab to 24.5 in Tamil Nadu, but in some blocks the average is less than 1 vaccination per day. Vaccinator salary costs alone average 0.47 rupee (US\$0.06) per vaccination, but in 3 blocks they exceed 7.5 rupees (US\$0.98) per vaccination.

- *Supervision*, except in Tamil Nadu, consists primarily in determining whether or not the vaccinator reports for work.

- *Vaccine* is improperly stored, inventories are inaccurate and refrigerators are frequently lacking or not in working order.

- The number of *reported cases* is estimated to be no more than 10% of the actual number and notification is considerably delayed except in Tamil Nadu, in which reporting appears to be reasonably complete. Many cases which are officially notified to state authorities are not subsequently reported to the national authorities. This deficiency in notification is illustrated by the situation in Punjab, in which state records to date in 1967 showed 1370 cases, of which only 273 had been notified at the national level.

- *Containment* measures are insufficient. For example, in a village in Uttar Pradesh, with a population of 250, 20 cases occurred; after containment, it was found that 20% of the unaffected children remained unvaccinated.

- Contrary to the findings of other reports, *vaccination acceptance* is good and the number of refusals for religious reasons is negligible. For the most part refusals stem from the unwillingness of people to be vaccinated at a time when a serious reaction might interfere with occupational responsibilities. Contributory factors are the tactlessness of some vaccinators, a crude vaccination technique and failure to inform people of the importance of vaccination. The rotary lancets waste vaccine (15 vaccinations are obtained from a vial of 0.25 ml compared with the 25–50 vaccinations obtained when the scratch technique is used); the lancets are difficult and time-consuming to sterilize and produce unusually severe local reactions.

- *Vaccination take rates* are said to be 100%, but assessment from records was possible only in Bombay. The records there show a take rate of 99.7%, but, in fact, failures were being re-

corded only after 3 unsuccessful attempts. The records show a maximum take rate of 77% after a single vaccination but it is probable that the actual take rate is considerably lower.

- The *family registers* everywhere are incomplete and contain numerous errors. They have been abandoned in Uttar Pradesh; in the Punjab and Maharashtra, in which a serious effort is being made to use them, vaccinators spend more than half their time on keeping them up to date.

#### *Levels of achievement*

- Smallpox incidence, the ultimate yardstick for measuring success, is noted to be rising. The total number of cases by the end of 1967 will represent the greatest incidence to be recorded in a decade. Even so, this total will represent 10% or less of the actual incidence.

- Cases are occurring in all age groups, although two-thirds or more in the states assessed are found in individuals under 15 years of age [Table 15.6].

- The proportion of the population reported to be receiving primary vaccination each year is less than 4% in all 4 states. With an estimated birth rate of 4% and many children born in previous years remaining unvaccinated, it is apparent that the number of susceptible subjects is accumulating.

- Sample surveys conducted among individuals under 15 years of age in randomly selected districts of the 4 states and wards of the cities of Madras (Tamil Nadu) and Bombay (Maharashtra) reveal widely different levels of performance [Table 15.7]. Uttar Pradesh has a higher proportion of unvaccinated children than was found in a survey conducted 10 years ago. In contrast, 90% of those in Tamil Nadu and 87% of those in the Punjab have vaccination scars. Vaccination levels in Madras and Bombay are substantially better than in the non-urban areas, a result attributed, in part, to the vaccination of children at birth (nearly 80% of them are born in hospital).

The team offered a detailed series of recommendations prefaced by the statement: "The Central Government should develop a new and long-term strategy to meet the

Table 15.6. India: age distribution of cases of smallpox in 4 states, 1967

problem." In brief, it recommended that greater emphasis should be given to case detection and the containment of outbreaks, especially during the summer months, when the incidence was lowest; and that primary vaccination, including the vaccination of newborn infants, should be given priority. An increase in the personnel complement of the national directorate from 1 to 5 professionals and a concomitant extension of their scope of responsibility were also recommended, along with the strengthening of supervision at all other administrative levels. It was suggested that vaccine production should be centralized and financed under national rather than state authority, that the use of liquid vaccine should cease throughout India, that the bifurcated needle should replace the rotary lancet, and that the family registers should be abolished.

### Progress Achieved in the Programme, 1968-1970

The recommendations of the joint assessment team were basically sound but smallpox eradication was not high among the government's priorities. Nevertheless, over the succeeding 3 years, the production of freeze-dried vaccine increased and its quality was improved, many laboratories producing liquid vaccine were closed, the bifurcated needle was introduced, the number of primary vaccinations increased, the vaccination of newborn infants was initiated in several areas, and in some states effective surveillance-containment programmes were conducted.

#### *Vaccine and the vaccination programme*

On the basis of WHO recommendations, Dr Singh stressed in a number of directives

the importance of primary vaccination, and, as from 1968, the proportion of the population reported to have been given primary vaccination increased significantly (see Table 15.4). However, even with the increase, this proportion barely exceeded the birth rate. At the same time, the total number of reported vaccinations declined steadily.

The vaccination of infants at birth was recommended as a national policy. Traditionally, primary vaccination in India had been deferred until children reached at least 3 months of age. Studies begun in 1959 by Dr A. R. Rao in Madras showed that the vaccination of neonates was safe and that systemic symptoms were minimal (Rao & Balakrishnan, 1963). With the liquid vaccine then in use, 80% were successfully vaccinated but, when freeze-dried vaccine and the bifurcated needle became available, this rate rose to more than 95%. It was clear that if vaccinators could vaccinate all children whom they encountered, overall vaccinal immunity would be enhanced. Equally important, higher levels of vaccinal immunity could be achieved in large urban areas, where 75-80% of women were delivered in a hospital or nursing home. Because the high concentration of people in urban areas played an important role in sustaining smallpox transmission, it was hoped that routine vaccination of newborn children in cities might have a significant impact in diminishing incidence throughout the country.

The routine vaccination of neonates began in Madras and Bombay in 1967 and in several other cities of Tamil Nadu in 1968. However, the practice was not enthusiastically pursued in most areas, partly because of the lack of interest shown by the autonomous municipal health officers and partly because mothers were reluctant to let their babies be vaccinated. They had observed in other children

the severe lesions induced by the rotary lancet and had had no opportunity to see the results of vaccination with the bifurcated needle.

From 1968 to 1970, efforts were made to increase the volume and quality of vaccine produced in India and to improve the distribution system and storage of the product. In 1969 the government appointed a central director for vaccine production and distribution, Dr S. N. Ray, and the following year, the 4 vaccine production centres were placed under central government authority and financed by central government funds rather than state funds. This simplified distribution, because vaccine produced in any one of the institutes could then be sent to any state of India without special payments being required. Previously, vaccine produced in each of the state laboratories had been used mainly in that state, while vaccine donated to India, primarily by the USSR, was sent to other states.

Vaccine production in India gradually increased in volume but less rapidly than had been expected. Not until 1974, in fact, did the country become completely self-sufficient (Table 15.8). In part, the delays could be attributed to preoccupation on the part of the director of the Patwardangar laboratory, the principal production laboratory, with the introduction of comparatively new, more elaborate machines for freeze-drying—the so-called shelf-driers. Relatively simple centrifugal freeze-driers were then in use in many countries and when installed in competent laboratories, as in Indonesia and

Kenya for example (see Chapter 11), could be used at full capacity within a year. The director justified the need for the shelf-driers on the grounds that extremely large quantities of vaccine would be required, estimating the need for far greater amounts than had been used during the 1962–1966 mass vaccination campaign. Moreover, he argued that the bifurcated needles, although they used less vaccine and had been adopted in most other countries, would never be acceptable in India. WHO smallpox eradication programme staff, however, foresaw the need for smaller quantities of vaccine, especially if the bifurcated needles could be used, and argued for the purchase of the less complex centrifugal driers. After an impasse lasting almost a year, a staff member of the WHO regional office, who was responsible for providing advice to laboratories, gave approval for the purchase of the shelf-driers, although he himself was not competent in vaccine production. With the promise of purchase of the shelf-driers, the laboratory director gave approval for studies of the bifurcated needle to be undertaken in India (see below). As had been feared, the shelf-driers proved difficult to operate and production increased only slowly but, because of the introduction of the bifurcated needle and the continued provision of vaccine by the USSR, vaccine shortages did not occur.

With an assured supply of freeze-dried vaccine available throughout India, it became possible for the government to insist on the cessation of production of the thermolabile

Table 15.8. India: number of ampoules<sup>a</sup> of freeze-dried vaccine produced each year, 1962–1977, by vaccine production centre, and donated vaccine distributed, 1970–1974

<sup>a</sup> With the rotary lancet, the contents of 1 ampoule were required to vaccinate 12–15 persons. When the bifurcated needle was used, the same quantity of vaccine sufficed to vaccinate as many as 100.

<sup>b</sup> The USSR donated from 5 to 6 million ampoules of vaccine annually beginning in 1962, but data regarding the distribution of this vaccine are not available before 1970–1971.

liquid vaccine. However, closure of the 14 state institutes which produced it proved to be difficult. The central government lacked the necessary authority; one by one, each state and centre had to be visited by officials of the central government and persuaded to cease production. This was finally accomplished in 1970, the last centres being in Calcutta and the eastern states. Even after closure of the production centres, however, problems remained. In several states, the stocks of liquid vaccine occupied all the available refrigerated storage space and, without the sanction of the finance department to destroy the vaccine, programme officers could take no action. Accordingly, in several areas, including Bihar State, in which smallpox was eventually to prove a major problem, stocks of freeze-dried vaccine continued to be stored at room temperature while the obsolete liquid vaccine was kept under refrigeration.

The provision of satisfactory refrigerated storage for vaccine was a continuing problem in other areas as well. The freeze-dried vaccine was supposed to be kept at ambient temperature for not more than 30 days but could be stored almost indefinitely at temperatures of 4 °C or less. Because, for reasons of logistics, most vaccinators could obtain vaccine supplies only once a month, it was important to ensure that vaccine stored in district offices, as well as in the state and national depots, was kept under refrigeration. Satisfactory storage at state and national distribution centres was gradually achieved through the provision of refrigerators by UNICEF and WHO and through the use of other facilities such as cold-rooms normally used for the storage of fruit and vegetables. In the districts, however, satisfactory storage was uncommon. Although virtually all district offices were provided with refrigerators for the storage of drugs and vaccines for a variety of programmes, few were maintained in working order. For example, as late as 1975, 85% of the refrigerators in district offices in Uttar Pradesh were found to be inoperative. Fortunately, as tests of vaccine showed, much of the vaccine produced in the USSR and India maintained levels of potency adequate for primary vaccination even after 3-4 months at high ambient temperatures (Sehgal, 1974; Sehgal & Ray, 1974).

The assessment team had also recommended that at least one-third of all batches of vaccine produced and tested in the separate

laboratories should be independently tested by a national vaccine control laboratory and that the results should be confirmed by a WHO smallpox vaccine reference centre (National Institute of Public Health, Bilthoven, Netherlands). In 1969, an Indian central control laboratory was established at the National Institute of Communicable Diseases, New Delhi, although it was not until 1972 that the laboratory actually monitored the recommended number of batches. In 1969, some batches of vaccine also began to be sent to the WHO reference centre for testing. During the period 1969-1976, of the 241 batches tested by WHO only 9 (3.7%) were found to be substandard (Basu et al., 1979). Although these data would suggest a consistently high level of satisfactory production, it must be noted that all batches dispatched to WHO had been determined, first by the production laboratory and then by the central control laboratory to be completely satisfactory. The producers and the central testing laboratory found a much higher proportion of batches of vaccine to be of inferior potency or stability or unacceptably contaminated with bacteria. Some such batches were destroyed but, in the first few years, most were distributed anyway because vaccine was in short supply. Properly, it was considered preferable to use substandard freeze-dried vaccine than to use liquid vaccine or to have no vaccine at all. No compilation of data on vaccine quality is available, but it was known that the Hyderabad and Guindy laboratories both had persistent difficulties in producing satisfactory vaccine. However, together they accounted for less than one-fifth of all vaccine distributed in India and most of the vaccine they produced was distributed to states in southern India in which health services were generally better and smallpox incidence was lower.

The improved quality of vaccine and a better storage system undoubtedly resulted in a higher proportion of successful vaccinations in the field, although no data are available to substantiate this.

#### *Introduction of the bifurcated needle*

The bifurcated needle had been tested by WHO in late 1967 and early 1968 and was rapidly made available throughout most countries by the middle of 1968. In India, however, the traditional rotary lancet had

been in use since before the turn of the century and a number of prominent senior health authorities as well as the director of the vaccine production laboratory in Patwadangar resisted the introduction of the new instrument. They argued that it would produce fewer successful vaccinations, that vaccinators would find it too difficult to use, and that the population would resist vaccination with an unfamiliar device. Finally, it was agreed that comparative studies of the two instruments would be undertaken by the National Institute of Communicable Diseases and the Central Health Education Bureau (WHO/SE/70.16).

In 1969, the National Institute assessed the efficacy of the two techniques (Pattanayak et al., 1970). In one study, previously vaccinated children were vaccinated on one arm with the rotary lancet and on the other arm with the bifurcated needle. Vaccines of three different levels of potency were employed. The results showed that the bifurcated needle had a clear-cut advantage over the rotary lancet (Table 15.9).

Comparative data derived from a study of a small number of children given primary vaccination showed similar results. It was found that vaccinators readily learned the new technique and used it successfully.

During the same period, the Central Health Education Bureau investigators assessed the acceptability of the new technique, with surprising results. Persons in 5 villages were vaccinated with the bifurcated needle, but they were given no explanation about the new device. One week later, the vaccines were examined to determine the proportion with successful vaccinations and were interviewed about the new technique. All those given primary vaccination, and 79% of those who had been revaccinated, had successful takes. As the investigators noted, "surprisingly, few realized that the technique applied was different from the customary rotary lancet method" (WHO/SE/70.16). With

these results, the needle was accepted by the national health authorities for use in India.

Needles were provided by WHO in large numbers and, by late 1969, they were in wide use in many states. However, the adoption of the new technique required that a decision should be taken separately by each state and municipality, and some were not persuaded. Not until 1971, for example, were the needles used in the states of Uttar Pradesh and Bihar. In many municipalities, vaccinators continued to use the rotary lancet until late 1973, when municipal smallpox eradication staff were brought under state jurisdiction.

The use of the bifurcated needle, however, brought a curious and unforeseen administrative problem. Auditors in India continually scrutinized the number of vaccinations performed in an area and compared it with the number of vaccinations reported in order to detect wastage. The vials of vaccine containing 0.2 ml allowed for only 15 vaccinations if the rotary lancet was used. With the bifurcated needle as many as 100 vaccinations could be performed with the contents of one vial, but in practice, an average of only 40-50 vaccinations was achieved because whatever reconstituted vaccine remained at the end of the day was supposed to be discarded. Although, in fact, more vaccinations were performed per vial supplied, the auditors calculated that each vial should now yield 100 doses of vaccine. Their assertions that vaccine was being wasted were to plague smallpox eradication staff throughout the rest of the programme.

#### *Sample surveys to determine vaccination status*

In 1969, the technique for vaccination scar surveys which had been developed in Afghanistan (see Chapter 14) was introduced into India. Through such surveys it was hoped that responsible officials would identify for themselves deficiencies in their vaccination programmes and correct them.

Table 15.9. India: results of simultaneous revaccination of children with the rotary lancet and the bifurcated needle

Vaccine potency (pock-forming units/ml)	Number of children	Rotary lancet	Bifurcated needle
		Number (%) with satisfactory response	Number (%) with satisfactory response
$1 \times 10^8$	84	22 (26)	47 (56)
$5 \times 10^7$	82	10 (12)	29 (35)
$1 \times 10^7$	81	10 (12)	26 (32)

The simplified methodology for scar surveys, using a cluster sample technique, was enthusiastically received in many states and numerous surveys were undertaken, some of which were state-wide. Not all the surveys were well designed, but the results consistently revealed a remarkably high proportion of vaccinated persons. The surveys showed that vaccination scars were borne by 92-99% of individuals in the age group 5 years and above; by 78-92% of those aged 1-4 years; and by 10-60% of infants under 1 year. Although the results were dutifully compiled and reported, few used the data constructively to identify populations or areas in which vaccinal immunity was low and to improve performance in such areas. The idea of assessing vaccination status in this way was reasonable but, in retrospect, the approach was probably counter-productive in that it served to reinforce the notion that mass vaccination was the principal foundation of the programme, rather than surveillance-containment measures.

#### *The decline in smallpox incidence*

Between 1967 and 1970, the reported number of smallpox cases fell dramatically—from 84 902 to 12 773, the lowest total ever recorded in India. Both government and WHO staff recognized that this reflected, at least in part, the normal periodic fluctuations of smallpox. Peaks in smallpox incidence in India normally occurred every 4-7 years, a periodicity extending back many decades. The peak in 1967 occurred just 4 years after the peak in 1963, which had been preceded, 5 years before, by the peak in 1958. This pattern was said to occur as a result of the gradual increase in the number of susceptible persons because of the waning of immunity in the population at large and the addition of susceptible newborn children. It was believed that when a sufficient number of susceptible persons had accumulated, an epidemic would ensue which would diminish this pool of susceptible individuals and thus the ease with which smallpox could spread. Following the epidemic, smallpox incidence would again decline. The decrease in the number of reported cases between 1967 and 1970 was thus not unexpected, but because the incidence had fallen to such low levels, some government and WHO staff were both optimistic and, to a certain extent, unduly satisfied with progress in the redirection of

the programme. The archaic notification system, with its delays in reporting, only served to reinforce this optimism. By mid-January 1971, for example, only 8026 (63%) of the 12 773 cases eventually recorded for 1970 had been reported to the Central Bureau for Health Intelligence.

#### *Southern India, 1967-1970*

The decline in smallpox incidence between 1967 and 1970 was especially notable in the 6 states and 5 union territories which formed the entire southern part of India. This area had a population in 1967 of 196 million (38% of the national total). The number of cases fell from 42 633 in 1967 to only 795 in 1970. Many districts reported no cases in that year (Fig. 15.5) and none was detected in the entire state of Tamil Nadu (population, 41 million) (Table 15.10).

In part, this decline was attributable to a generally more developed health service structure, especially in the states of Kerala and Tamil Nadu and, in consequence, a better execution of the mass vaccination campaign. It was also associated with the development of an effective surveillance-containment programme—first in Tamil Nadu and later in parts of Andhra Pradesh.

To evaluate the applicability of surveillance-containment in India, it was decided in 1968 to investigate and contain all outbreaks in Madras, the capital of Tamil Nadu, and subsequently in the state itself, employing a surveillance team directed by Dr A. R. Rao, then Health Officer of the Madras Municipal Corporation. Support for this operation was provided by the Indian Council for Medical Research and WHO (WIIO/SE/68.6 and WHO/SE/68.7, A. R. Rao). Dr Rao, for many years the Director of the Madras Infectious Diseases Hospital, had conducted extensive investigations into the clinical and epidemiological behaviour of smallpox (Rao, 1972). He was an ideal person for the task and interested in taking up the challenge.

Smallpox incidence in Tamil Nadu had declined sharply, from 8901 cases in 1963 to only 263 cases in 1967, of which 38 cases had been reported by the Madras Municipal Corporation. The joint India-WHO assessment team (1967) believed that reporting was better in Tamil Nadu than elsewhere in India and, if indeed there were as few cases as notifications suggested, it should be possible to stop transmission with a comparatively

modest outbreak containment programme. If successful, it would serve as an example for other states in India.

Between January and June 1968, the season of highest smallpox transmission, Dr Rao investigated 13 outbreaks in Madras, which were detected when patients were brought to the hospital or when fatal cases were registered at the burial grounds. The source of 7 outbreaks could be traced, 6 of them coming

from adjoining states. Eight of the index cases were hospitalized within 10 days of onset and none of them spread the disease. Five of the infected persons were hidden at home and, before discovery, 8 second generation and 4 third generation cases occurred. However, the total number of cases was small and, as Dr Rao emphasized, smallpox did not spread rapidly in this population despite its high density and the season of the year. In mid-

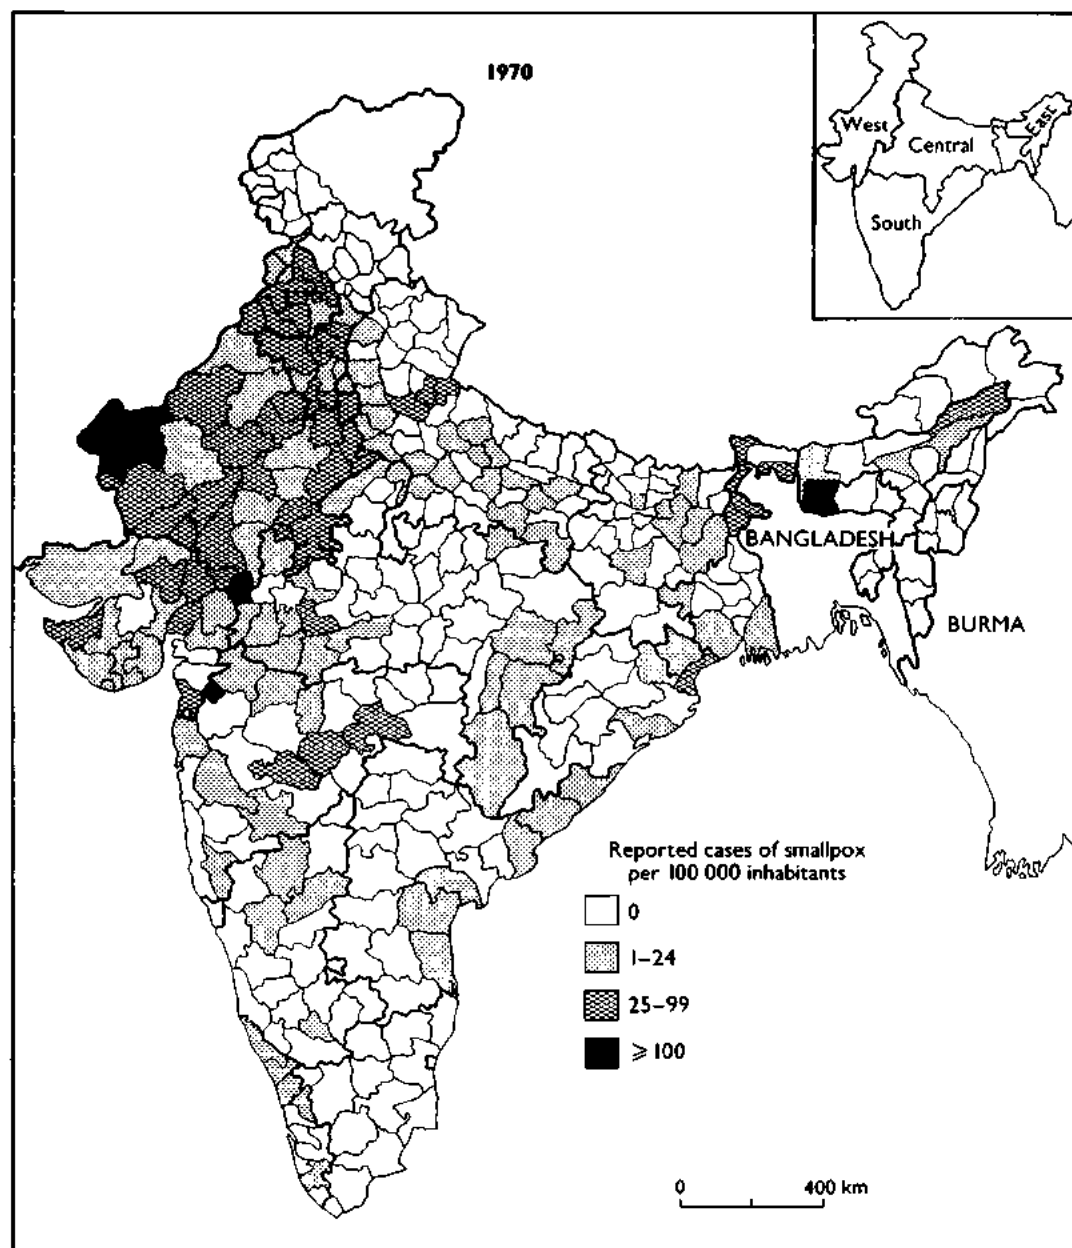

Fig. 15.5. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1970.

<sup>a</sup> No cases were recorded during this period in the union territories of Andaman and Nicobar Islands, Lakshadweep and Pondicherry.

<sup>b</sup> Became the state of Karnataka late in 1973.

June, the team began to extend its activities beyond the boundaries of the city. The investigation of a case brought to the hospital from a village 24 kilometres away revealed an outbreak of 44 cases in 5 villages. The outbreak had begun in January, when migrant workers returned from the neighbouring state of Andhra Pradesh. As in the city, smallpox had spread surprisingly slowly, suggesting again that outbreaks might be readily controlled. Between July 1968 and June 1969 only 2 additional outbreaks were found in all of Tamil Nadu: one comprised 6 cases imported from Madhya Pradesh State, and the other involved a single patient who had been infected in Gujarat State (WHO/SE/70.19, A. R. Rao). Transmission in Tamil Nadu had been interrupted less than 6 months after a single surveillance team had begun its work; after May 1968 the state remained smallpox-free except for importations.

The Madras team had little to do and so, in October 1969, with the agreement of the authorities in the neighbouring state of Andhra Pradesh (population, 43 million), Dr Rao investigated outbreaks in coastal villages 160 kilometres north of Madras. In all, he documented more than 200 cases in the poorly vaccinated population of a group of fishing villages (WHO/SE/70.17, A. R. Rao et al.). This, in turn, stimulated surveillance activity on the part of the state authorities of Andhra Pradesh. The number of cases in Andhra Pradesh diminished from 7951 in 1968 to 1893 in 1969 and to 358 in 1970. However, transmission persisted, primarily among the fishermen and their families, who migrated seasonally from this area northwards to Orissa State.

The success of surveillance and containment measures in both Andhra Pradesh and Tamil Nadu was dramatic, but, despite Dr Rao's presentations at subsequent national and international meetings, little notice was taken of the achievement. The state smallpox eradication programme officer who accompanied Dr Rao to the meetings rightly noted that the vaccination campaign in Tamil Nadu had been exceptionally well executed, but he argued that it was for this reason, and not because of the surveillance-containment activities, that transmission had been interrupted there. Authorities in other states dismissed the attainment as not surprising in the generally more prosperous southern states and of no applicability to most of the rest of India.

#### *Western India, 1967-1970*

Although progress in southern India gave cause for optimism, the number of reported cases of smallpox doubled in the western state of Gujarat (population, 27 million), increasing from 3403 cases in 1967 to 7654 in 1968. The epidemic continued into 1969, when 6284 cases were recorded—i.e., one-third of all cases reported in India (Table 15.11) and, in fact, almost one-fifth of all cases reported throughout the world.

WHO proposed to the government of India that a team should visit Gujarat to assess the situation. The government agreed, albeit reluctantly, to a 1-week field trip. Since the 1967 India-WHO assessment of the programme, field visits by WHO Regional Office staff, although resident in New Delhi, had been discouraged. It was the government's view that WHO staff could

Table 15.11. Western India: number of reported cases of smallpox, 1967-1970

contribute little to a programme that was directed by a national staff who had been engaged in eradication since 1962. Field visits by national staff were likewise uncommon, Dr Singh rarely being able to leave New Delhi because of his innumerable responsibilities. Moreover, his authority was circumscribed because the responsibility for programme execution rested primarily with the states.

In April 1970, a 3-man team, comprising Dr Andrzej Oles, from the WHO Regional Office for South-East Asia, Dr Singh and Henderson, visited Gujarat State and its capital, Ahmedabad (population, 1.7 million). The epidemic in Ahmedabad was considered by local staff to have begun in November 1969 and, to combat it, 150 temporary vaccinators had been hired to supplement a staff consisting of 1 supervisor (medical officer), 39 vaccinators and a 6-man "flying squad". This provided 1 vaccinator for approximately every 9000 persons. The hiring of large numbers of temporary vaccinators without additional supervisors was a common response throughout India to epidemic smallpox. Between January and March 1970, more than 360 000 people had been vaccinated but the number of reported cases continued to increase. The Deputy Director of Health and Medical Services, Dr G. J. Ambwani, had done a commendable job in improving the facilities for vaccine storage and distribution and in introducing the bifurcated needle. Vaccinal immunity was found to be high in all areas which the team visited. The containment of outbreaks was prompt but poorly executed. The team found many additional unreported cases and in none of the outbreaks had an effort been made to identify the source of infection and, thereby, additional outbreaks. Although local

civil authorities were responsible for case reporting, almost all the cases were reported by vaccinators.

More disturbing was the discovery that the large numbers of cases reported were not reflected in reports to the national authorities. It was found that the Central Bureau for Health Intelligence had recently informed state statistical sections that it wanted a final report from all districts within 3 weeks of the notification of an outbreak. In Gujarat, this was interpreted to mean that any additional cases that were found after this period or any cases that had experienced the onset of illness more than 3 weeks previously should not be reported to the Central Bureau. The cases were, however, recorded by the state's smallpox eradication programme office. Not only was the epidemic in Gujarat of a far greater magnitude than had been suspected, but the discovery that this new policy had been adopted led to the suspicion that India's remarkable decline in incidence might possibly be an artefact caused by a reporting system distorted by misguided or misunderstood directives.

The team concluded that cases were occurring predominantly among a small, unvaccinated segment of the population, amounting to not more than 5-10% of the total, primarily in slum areas and among migrant labourers.

After just 5 days' work in the field, Dr Ambwani realized that he had not previously understood the surveillance-containment strategy and promised to implement such a programme forthwith. Working with the state smallpox eradication programme officer, Dr S. D. Verma, he was remarkably successful. The numbers of cases declined rapidly and in June 1971, only 14 months after the team's visit, transmission ceased.

D. A. HENDERSON, 1970

**Plate 15.3.** Members of an Indian/WHO team to assess the smallpox epidemic in Gujarat State in April 1970. Left to right: Andrzej J. Oles (b. 1923), an epidemiologist with the WHO Regional Office for South-East Asia; Mahendra K. Singh; and G. J. Ambwani, Deputy Director of Health and Medical Services of Gujarat State.

Other cases occurred later but they were traced to importations from other states. The success in Gujarat suggested to both senior Indian and WHO staff that if states were given modest assistance to foster surveillance-containment programmes, these results might be replicated elsewhere. Unfortunately, Gujarat, like Tamil Nadu, was to prove an exception.

The team returned to New Delhi encouraged by Dr Ambwani's interest in and responsiveness to the surveillance-containment strategy but now less confident that the remarkable decline in the number of reported cases was real. A recommendation was made that the reporting system should be changed but this was vigorously resisted by the director of the Central Bureau for Health Intelligence. Thus, the programme continued, its personnel less certain of the true incidence of smallpox but now placing increased reliance on data provided by state eradication programme officers rather than on official government statistical reports. However, because the quality of the programme officers varied greatly from state to state and because the Central Bureau's directives were variously interpreted by officials at different levels, it was difficult to know what the different sets of numbers really meant without field visits to every state—and no staff were available to undertake such visits.

Yet another disturbing observation was made in the western states in the spring of 1970. It began to appear that smallpox might be moving as an epidemic wave in a clockwise direction around India. In 1967, immediately before the 1968–1969 Gujarat epidemic, Maharashtra, the state immediately to the south, had reported especially severe epidemics. That year, it had recorded 27 961 cases, one-third of all cases reported from India. The number dropped to 3173 in 1968 and to 1411 in 1969. In the spring of 1970, the states of Rajasthan and Haryana, immediately to the north of Gujarat, began to experience major epidemics.

This had not been expected. Since the 19th century, major epidemics in the Indian subcontinent had been observed to occur every 4–7 years, but the periodic fluctuations had been thought to take place more or less simultaneously throughout the country. The wider availability of vaccine had not altered this pattern. That the periodicity had persisted until 1962 was understandable because intensive and widespread vaccination had been conducted during and immediately after epidemics, but as smallpox waned so did interest in vaccination. However, it was quite unexpected that the intensive ongoing national vaccination campaign begun in 1962 had not prevented the 1967 epidemic. To explain this recurrence, it was suggested that many states had not conducted effective

campaigns, and because much of the vaccine used had lacked potency, the large pool of susceptible persons had not significantly diminished. Between 1967 and 1970, however, most of the vaccine reaching recipients was believed to be fully potent and because the number of primary vaccinations had substantially increased, the opinion was held that India should not again experience a major epidemic year. Thus, the recurrence of epidemic smallpox, apparently moving in a clockwise direction around India, was totally unexpected but a critical factor in the formulation of subsequent strategy.

In 1970, senior national government staff began to take a greater interest in the smallpox eradication programme. Epidemic areas in Haryana and Rajasthan abutted on New Delhi, the national capital. Reports of the outbreaks appeared in increasing numbers in New Delhi newspapers, and members of Parliament expressed concern through "call-attention" motions, obliging the government to give an account of what was being done.

The Gujarat team had concluded in its recommendations to the government: "... of greatest importance ... is the need to augment the staff at state level to provide leadership to the programme and to develop and coordinate, by active field work, the very critical surveillance-containment activities." WHO proposed to the government that 4 WHO epidemiologists should be recruited to work as advisers with state programme officers. One would be assigned to Rajasthan, in which smallpox incidence was rapidly rising; one each would be allocated to Uttar Pradesh and Bihar, the two densely populated states comprising most of the northern Ganges river plain, and, if assumptions regarding the clockwise movement of epidemic smallpox were correct, the next to experience major epidemics; the fourth epidemiologist would be assigned to work with state programme officers throughout the southern states in an effort to interrupt transmission in this vast area. Dr Singh, meanwhile, would plan to work with programme officers in the small neighbouring states of Haryana, Punjab and Himachal Pradesh as well as the Delhi Municipal Corporation.

The Director-General of Health Services and the Secretary of Health were initially of the opinion that 2 advisers would suffice but ultimately agreed to 4. On 9 September

1970, an agreement was signed by the government and WHO which committed WHO to provide: (1) 4 epidemiologists and 3 short-term consultants for 3 months each in 1970 and 1971, plus the costs of their travel; (2) vehicles and other supplies; and (3) funds to pay salaries, travel and per diem "for additional personnel employed full-time in smallpox units at the national and state levels up to the limit of Rs. 1 125 000 each year" (US\$146 250). In 1970, WHO support to the programme for the first time exceeded US\$100 000. During the succeeding 7 years, more than US\$11 million would eventually be provided, most of which represented contributions from the government of Sweden (Table 15.12). Additional funds were allocated to the WHO Regional Office for South-East Asia, which as the Indonesian programme concluded, began to devote more time to the programme in India.

#### The Foundations are Laid for the Intensified National Campaign, 1971-1973

From 1971 until the summer of 1973 the programme gradually evolved and, in doing

<sup>a</sup>Expenditures by the central government (1965-1969) and state governments (1965-1972) are estimates. Of funds expended by WHO between 1974 and 1977, US\$8.1 million were provided by the Swedish International Development Authority.

<sup>b</sup>Excludes the estimated value of vaccine provided between 1965 and 1974, which amounted to 701 million doses from the USSR and 5 million doses from WHO.

<sup>c</sup>Value of contributions in cash and in kind from Tata Industries (US\$600 000), USA (US\$402 000), UNICEF (US\$380 000), and OXFAM (US\$100 000).

**Plate 15.4.** A: Alberto M. Monnier (1914–1979), an epidemiologist, served as the WHO smallpox officer in Rajasthan State from 1971 to 1976. B: Viatcheslav A. Moukhopad fulfilled the same role in Uttar Pradesh State from 1971 to 1976.

so, laid the foundations for the intensified national campaign, termed "Smallpox Zero", which began in the autumn of 1973. A closer working relationship was established between the government of India and WHO; the bifurcated needle replaced the rotary lancet in all but a few municipal corporations; the use of liquid vaccine ceased completely; larger quantities of good-quality freeze-dried vaccine produced in India became available; the reporting system was changed; and a procedure for the detection of cases was elaborated.

WHO recruited 2 new regional smallpox advisers, for what was then called the Regional Epidemiological Surveillance Team, as well as 4 epidemiologists for assignment to India. Dr Nicole Grasset, a French virologist and epidemiologist, became the regional adviser in 1971, replacing Dr Keja, who had been transferred to Indonesia. She had worked previously in smallpox and measles control activities in eastern Nigeria and had proved to be a charismatic leader. She was joined in the regional office in 1972 by Ježek as the second regional adviser. Although they were responsible for smallpox eradication activities throughout the South-East Asia Region, much of their work was to be devoted to the programmes in India and Nepal. The 4 epidemiologists for the programme in India were assigned to the states. Dr Alberto Monnier, a Mexican epi-

demologist who had been with the Indonesian smallpox eradication programme, began work in Rajasthan in January 1971 and Dr V. A. Moukhopad, a Soviet epidemiologist, arrived a month later to begin work in Uttar Pradesh. That summer, a Czech epidemiologist, Dr Vladimir Zikmund, began work in the southern states. Another epidemiologist reported for duty in Bihar during the summer but stayed only 6 months before resigning. At that time, the post in Bihar was felt to be the least critical, since the available data for 1971 showed smallpox was then concentrated in the north-western part of the country (Fig. 15.6), geographically distant from Bihar. A principal problem in Bihar, as well as in the other states, was the stipulation that each state should provide a vehicle for each adviser and cover the costs of its operation. Rarely before had WHO staff been assigned to work at state level in India and, with vehicles in the states in short supply and poorly maintained, the provision of transport for the advisers was a problem. In Bihar, none was made available and, in general, state officials showed little interest and offered the minimum of cooperation in helping to solve difficulties of this kind. Not until 2 years later were the inadequacies of the Bihar health structure fully appreciated. Conceivably, more energetic measures in Bihar at that time might have averted the catastrophe that lay ahead.

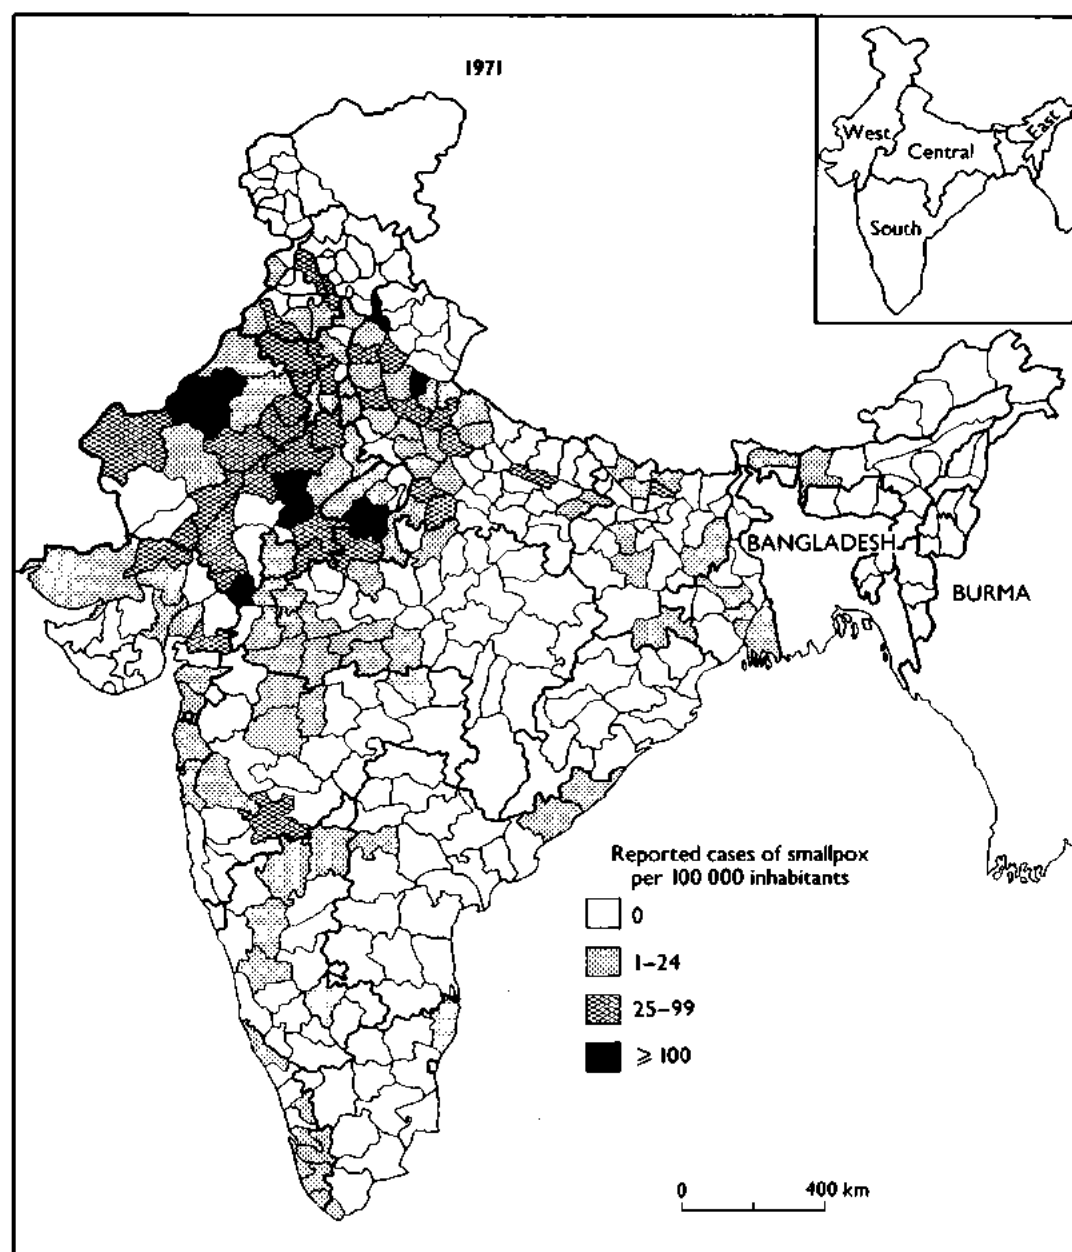

Fig. 15.6. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1971.

Smallpox eradication activities continued in all states throughout 1971–1973, with varying levels of success. During this period there were developments of particular note in the western states and in Uttar Pradesh, as well as in certain of the areas of low incidence in the south, and an unanticipated setback originating in a Bangladeshi refugee camp in West Bengal. These are described below.

#### *Western India, 1971–1973*

It had been hoped that the dramatic success of the surveillance–containment programme in Gujarat might be repeated in the other western states and in Uttar Pradesh, in which epidemics were then beginning. Dr Monnier, assigned to Jaipur, the capital of Rajasthan, and Dr Moukhopad, assigned to Lucknow,

the capital of Uttar Pradesh, provided needed support. Full-time assignments were deemed advisable: in Rajasthan because health and other services were less well developed in this conglomerate of former princely states than in most of India; and in Uttar Pradesh because of its vast population (91 million) and its dismal performance during the mass vaccination campaign.

Rajasthan, besides having a less adequate structure of health services and a less literate population than much of India, was geographically a problem, nearly two-thirds of its area being desert and semi-desert. Roads were few and working conditions demanding. The population of 26.5 million was principally settled in 151 towns and 33 305 villages, but there were nomads as well. Three state teams were created which were directed, respectively, by the Deputy Director for Communicable Diseases, Dr M. L. Aggarwal; his deputy, Dr D. K. Jagdev; and Dr Monnier. Each was assigned a paramedical assistant. Vehicles were made available sporadically for the state officials but Dr Monnier used his private car for almost a year until it was agreed that WHO would provide him with a vehicle. In addition to training district and local staff in reporting and containment measures during their extensive travels and in specially convened meetings, the teams undertook to detect and contain outbreaks.

As in other countries, the discovery of suspected cases was usually accomplished by questioning village leaders, schoolteachers and their pupils, and people attending weekly

markets. In Rajasthan and in many other parts of India, there were two additional methods, unique to India, by which cases could be detected. One consisted in questioning visitors to the Sitalā mata temples. Many villagers came to give thanks to the goddess for recovery from smallpox or to offer homage in the hope that they and their families would be spared a visitation by the goddess. Cases could also be detected in villages when, as was customary in many areas, branches from the neem tree were hung over the front door of a house in which a patient lived. The leaves of the neem were considered to have special cooling properties when applied to the skin of the patient and other, less tangible, properties when hung above the doorway.

The programme in Rajasthan made commendable progress. At the beginning of the summer of 1971, the number of reported cases declined steeply, and the incidence remained comparatively low during the spring smallpox season of 1972 (Fig. 15.7). In October, in order to strengthen the programme, other health workers, such as the family planning and malaria eradication programme staff, were directed to report any smallpox cases found during the course of their work. A further decline in incidence occurred in 1973 (Table 15.13), and from August to October 1973 no cases whatsoever were detected. Cases occurred subsequently in Rajasthan, but they originated from importations. The results were impressive and what had been hoped for, although the programme was undoubtedly assisted, as in Gujarat, by a decline in incidence associated with the longer-term fluctuations of smallpox. Nevertheless, little more than 2 years had elapsed between the time the surveillance teams

had begun work and the unprecedented occurrence of 3 months without detectable smallpox.

Dr Singh, through such visits as he could make to the western states near New Delhi, was no less successful in stimulating effective surveillance–containment programmes. The number of cases in the contiguous states of Haryana, Himachal Pradesh and Punjab and in Delhi Municipal Corporation (total population, 32 million) fell somewhat less steeply than in Rajasthan, but by the winter of 1972–1973 fewer than 100 cases were being detected monthly, many of which resulted from importations from the neighbouring state of Uttar Pradesh. By September 1973, transmission had been interrupted throughout this entire area, the only reported cases resulting from importations into New Delhi.

Meanwhile, the programme in Gujarat had progressed so satisfactorily that only 44 outbreaks were detected during the first 6 months of 1971, and none whatsoever from July to the end of October. It seemed impossible that transmission could have been stopped in a state so heavily infected as recently as 1970. Accordingly, Arita was

asked to direct a special assessment of the state in November 1971. During a 3-week period, he led a 6-member team which visited 90 towns and villages in high-risk areas of 11 districts. No evidence of smallpox since June of that year could be found. The success reflected, in part, improved case detection and containment of outbreaks, but intensive vaccination undoubtedly also played a role. District surveys in September 1971 revealed that vaccination scars were present in 98–99% of those aged 5–14 years, in 96–99% of those aged 1–4 years and in 66–88% of those aged less than 1 year.

The smallpox eradication programme throughout the western states was progressing everywhere as had been hoped (Fig. 15.8) with a single exception—the northern state of Jammu and Kashmir (population, 4.8 million), which had once been free of smallpox. In the autumn of 1972, the state began reporting increasing numbers of cases. Until October, Jammu and Kashmir had experienced only occasional importations which, according to state reports, had been quickly contained. It had been hoped that by preventing smallpox from becoming re-established in Himachal Pradesh, a geo-

graphical barrier to the northward spread of the epidemic would be created, preventing the disease from reaching Jammu and Kashmir. Dr Singh, working with effective state programme staff, proved successful in maintaining the non-endemic status of Himachal Pradesh. Unfortunately, many travellers to Jammu and Kashmir imported smallpox from infected areas more than 50 kilometres away. Because of the paucity of senior smallpox advisers, assistance had not been provided to state staff in Jammu and Kashmir and the health services had been unable to cope. The failure to strengthen activities in this state was an omission for which the programme would subsequently pay dearly in additional effort.

#### *Uttar Pradesh, 1971-1973*

The development of surveillance-containment programmes in the western states proved to be comparatively straightforward, but in the adjacent state of Uttar Pradesh, the experience was entirely different. Uttar Pradesh was India's most populous state (population, 91 million) with a density of 300 persons per square kilometre. Most of the state comprises the Ganges river plain, where population densities were among the highest in India and where transport and communication services were quite well developed. There was an extensive, well-established infrastructure of health services and a large, reasonably well trained health staff. In retrospect, unexpected problems might perhaps have been foreseen because of Uttar Pradesh's poor performance in the mass vaccination campaign, and because it was the last state in India to replace the rotary lancet with the bifurcated needle (1971).

During 1971, Dr Moukhopad and the state programme officer travelled extensively to conduct regional training programmes for all district health officers and their programme staff. However, almost as soon as they were trained in reporting and in surveillance-containment procedures, they were transferred to other districts or assumed other duties. Many who reported substantial numbers of cases of smallpox from their districts were disciplined by the state Director of Health Services by being transferred to hardship posts on the grounds that the presence of cases was tacit evidence that they had not conducted an effective vaccination

campaign. Although other states followed this practice, none did so as frequently as Uttar Pradesh and neighbouring states in northern India. Continuing efforts were made by national staff and WHO advisers to persuade state officials that their actions were counter-productive, but with only partial success.

Progress in the programme in Uttar Pradesh was difficult to assess, in part because of the suppression of reports by district officers and in part because of the archaic state and national reporting system. During 1971, the number of cases reported from Uttar Pradesh to the Central Bureau for Health Intelligence never reached 500 per month, and indeed between July and September of that year fewer than 100 cases were notified each month for the entire state. The relevant data, reported to the Central Bureau and to WHO up to 26 October 1971, are shown in Table 15.14 (*Wkly epidem. Rec.*, 1971b). Even if one were to assume that there were 10 times as many cases as had been reported, not only Uttar Pradesh but India as a whole appeared to have very few chains of smallpox infection. On the basis of a growing experience with surveillance-containment programmes, it seemed reasonable to expect that transmission could be interrupted comparatively easily and rapidly. The greatest impediment in assessing the true situation and in deciding how best to deploy resources to achieve this goal was the reporting system.

In November 1971, the government and a new acting director of the Central Bureau for Health Intelligence agreed to modernize the reporting system so that its procedures would resemble those used in other countries. Each primary health centre was directed to notify to the district on Saturday of each week the total number of cases detected that week irrespective of the date of onset. If no cases were reported, a "nil" report was to be submitted. The submission of a nil report was a most important feature. Previously, the absence of a report had been assumed to mean an absence of cases when, in fact, the responsible medical officer may have been negligent in reporting or had decided not to report because there were a great many cases. Officials who had been accustomed to suppressing information through the simple expedient of not submitting a report found it difficult to indulge in deliberate falsification. The districts were asked to ensure that reports from all primary health centres were

<sup>a</sup> Data reported to WHO up to 26 October 1971 (*Wkly epid. Rec.*, 1971b). . . = data not recorded.<sup>b</sup> Population estimates by state are based on United Nations (1985) data for all of India proportionately allocated by state on the basis of the 1971 census.<sup>c</sup> No cases were reported during this period in the union territories of Andaman and Nicobar Islands, Dadra and Nagar Haveli, Lakshadweep, Pondicherry, and Mizoram, and the state of Meghalaya.<sup>d</sup> Became the state of Karnataka late in 1973.<sup>e</sup> Became the union territory of Arunachal Pradesh in 1972.

submitted and to compile all reports then available on the following Tuesday and to send them to the state smallpox eradication programme office. The state, in turn, was made responsible for ensuring that all districts reported and, on each Thursday, for telegraphing a report to the Central Bureau for Health Intelligence and the National Smallpox Eradication Programme office. Many months, and in some states several years, of work were required before the reporting system functioned well but a major obstacle to the achievement of eradication in India had at last been removed.

In November 1971, Uttar Pradesh was the first state to implement the new reporting scheme. By February 1972, the number of districts which had not reported for 3 weeks or more had fallen from 17 to only 5, and by summer, 48 of the 55 districts were submitting reports promptly each week. Whether because of improved reporting or

because of an actual increase in incidence, the number of recorded cases rose during the winter of 1971-1972 to between 1200 and 1600 each month (Fig. 15.9)—but still, in a population of 91 million, this was not a great number. Senior staff continued to believe that with sustained support to the surveillance-containment effort, Uttar Pradesh would repeat the experience of the western states. It was not to be. Smallpox eradication staff were diverted to perform cholera vaccinations between September and December 1972, at a time when the containment of smallpox outbreaks was most crucial. Although cholera vaccine had been shown to be of little value, this was the usual and politically acceptable response of the health services when cholera occurred. Explosive outbreaks of smallpox spread across the state; the number of cases increased rapidly during the early months of 1973, reaching a peak in May, when 5000 cases were reported.

Particularly discouraging was the continuing antipathy of state officials to the surveillance-containment strategy. An episode in early April 1973 in the district of Muzaffarnagar vividly illustrated the prevailing attitude. This district, located less than 100 kilometres north of New Delhi, began experiencing outbreaks of smallpox in the autumn of 1972 and, in January, reported 440 cases. This greatly exceeded the number reported that month by any other district of India except 2 districts in West Bengal associated with the Salt Lake Refugee Camp disaster (see later in this chapter). In February 1973, Arita joined Dr Moukhopad in a special investigation of the problem. Active searches at schools and markets soon revealed that although the reported smallpox incidence was high, there were many other undetected and uncontrolled outbreaks occurring throughout the district. With the cooperation of a responsible, energetic district health officer, they decided to mobilize all health staff throughout the district by closing the health centres and training the staff to undertake a 2-week systematic village-by-village search for cases. The health staff responded with enthusiasm and efficiency and soon discovered that cases were occurring in more than half the villages. In all, 641 cases were discovered in February and 1219 in March. Containment measures had scarcely begun, however, when the state Director of Health Services ordered

the cessation of all surveillance-containment operations and the immediate vaccination of the entire population of the district. He then warned that when this had been completed the report of any further cases would result in the transfer of the district health officer to the most unpleasant post in the state. It was clear that considerable persuasion of state officials and heroic efforts in the field would be required if Uttar Pradesh was to become free of smallpox. However, the demonstration that it was possible to mobilize effectively the poorly supervised army of health staff offered hope for the future.

#### *The southern states, 1971-1973*

In the southern states, it had been hoped that the WHO adviser, Dr Zikmund, working with state programme officers might succeed reasonably quickly in developing surveillance-containment activities to the point of interrupting transmission throughout the entire area. Tamil Nadu continued its successful programme and from the beginning of 1971 to the end of 1973 only 11 cases were recorded (Table 15.15), all following well-documented importations. Mysore (renamed Karnataka in 1973) and Andhra Pradesh, the contiguous states to the north, were targets of high priority. Virtually all cases in Andhra Pradesh occurred during the first half of 1971 among generally uncooperative, poorly vaccinated fishermen who migrated seasonally between Andhra Pradesh and Orissa. District health officials, considering them to be temporary residents, had ignored them. Once vaccination and outbreak containment began, transmission quickly stopped. In Mysore, 185 of the 223 cases reported during 1971 were from a single district and these outbreaks were contained by midsummer. Maharashtra was also successful in stopping transmission. In the entire southern area, between October 1971 and January 1972, only 45 cases were detected, all of them occurring in 3 districts. Considering that the southern states accounted for 38% of India's total population, there was reason for optimism about the prospects for the eradication of smallpox in India.

Uncertainty persisted, however, about the situation in the state of Kerala. There, smallpox transmission appeared to have been interrupted in 1967, only 42 cases, presumably importations, having been detected between 1968 and 1970. However, between January and May 1971, 105 cases were

Fig. 15.9. Uttar Pradesh State: number of reported cases of smallpox, by month, 1971-1973.

reported, with 1 additional case in September and 2 in November. Kerala's health services, among the best in India, reported that the cases had not occurred in outbreaks as one would expect, but rather were scattered across 7 of its 10 districts. Because the epidemiological pattern of the cases was difficult to explain, Arita joined state officials in a special study in February 1972. Of the reported cases, 70% were found to be in persons over 15 years of age, and of the patients whose vaccination status was known, 102 had previously been vaccinated. Arita and his collaborators examined 35 patients who had recovered, but none had the residual pockmarks typical of smallpox. As it turned out, the state in late 1970 had requested health staff to begin to collect specimens from patients with chickenpox as well as from those with suspected smallpox to confirm with greater certainty that the state was smallpox-free. A state laboratory with little experience in the identification of variola virus had examined the specimens using the gel-precipitation technique and reported that 104 out of 386 tested were either "positive" or "doubtful" for variola virus. Although there was little doubt on the part of physicians about the clinical diagnosis, the virological reports were accepted and the cases duly notified. The team eventually concluded that none of the reported cases was smallpox and the reports were retracted. Except for 4 imported cases in 1974, Kerala was to remain smallpox-free.

The findings in Kerala provided further encouragement but, in February 1972, it

suddenly became apparent that there were serious, hitherto unrecognized, problems in Mysore. The discovery of smallpox in Mysore was made by surveillance teams in the neighbouring state of Andhra Pradesh, whose programme was directed by Dr M. C. Appa Rao. There, case detection had improved significantly when, at the end of 1971, a sum of 10 rupees (US\$1.33) was awarded by the government for the discovery of a case—the first time in India that such a reward had been offered. The teams detected outbreaks in Hyderabad whose source of infection was a village in Gulbarga District, one of 19 districts of Mysore State. The outbreak was unknown to the Mysore state programme officer. The district (population, 1.7 million) had an extensive network of health facilities, including a large general hospital, 71 health centres and dispensaries, a medical college, and special programmes for the control of malaria, filariasis and tuberculosis and for family planning. It was assumed that if smallpox cases had been present, they would have been quickly detected. State officials, in collaboration with Dr Zikmund, began an immediate investigation. It soon became apparent that not one but numerous outbreaks had occurred, beginning almost 15 months earlier, in December 1970. By the end of March, the investigators had discovered 81 outbreaks and 730 cases. They found that even the staff members of primary health centres who lived in villages with major outbreaks had not reported them; many directors of primary health centres who were notified of cases dismissed them as chickenpox; and, indeed, the District Director of Health and Family Planning, who had been officially informed of smallpox cases as early as September 1971, had suppressed the reports. It was concluded that radical measures would be required to stop the epidemic.

Able leadership was provided by a newly appointed District Medical Officer of Health, Dr Rama Rao; health staff were transferred from other districts; and all health and family planning staff in Gulbarga District were mobilized to undertake repeated house-to-house searches for cases throughout the district. When outbreaks were discovered, they were promptly contained. New outbreaks rapidly decreased in number, from 34 in April to 12 in May and 4 in June. To counter the tendency to conceal cases, a reward of 25 rupees (US\$3.33) was offered to anyone who reported a case of smallpox.

Table 15.15. Southern India: number of reported cases of smallpox, 1971–1973<sup>a</sup>

State or union territory	1971	1972	1973
Andhra Pradesh	214	405	1 295
Dadra and Nagar Haveli	0	0	1
Kerala	0	0	0
Maharashtra	160	215	158
Mysore <sup>b</sup>	223	1 299	6
Orissa	16	5	1 276
Tamil Nadu	7	1	3
Total	620	1 925	2 739
Other states and union territories of India	15 570	25 482	85 375
Grand total	16 190	27 407	88 114

<sup>a</sup> No cases were reported during this period from the union territories of the Andaman and Nicobar Islands, Goa, Daman and Diu, Lakshadweep, and Pondicherry.

<sup>b</sup> Became the state of Karnataka late in 1973.

### Chickenpox—a Problem in Surveillance in Kerala

Cases of and deaths from severe chickenpox proved the most difficult in differential diagnosis. The most problematic cases were those in adults. Among residents of the southern state of Kerala (population, 24 million), as well as among migrants from that state, cases of chickenpox in adults occurred with unusual frequency, and this resulted in a number of erroneous reports and special investigations. In the process of confirming that transmission had been interrupted in India, a special study was conducted in Kerala to ascertain that the deaths attributed to chickenpox had been correctly diagnosed (White, 1978).

#### *Age Distribution of Deaths Due to Chickenpox, January 1975–March 1976*

<i>Age group (years)</i>	<i>Males</i>	<i>Females</i>	<i>Total</i>	<i>Prevalence per 100 000 of cases of chickenpox<sup>a</sup></i>
0–4	6	3	9	64
5–9	2	1	3	102
10–19	4	3	7	87
20–29	1	3	4	59
30–39	14	3	17	56
40–49	34	1	35	69
50–59	34	5	39	48
60–69	31	14	45	31
≥70	74	27	101	36
Total	200	60	260	71

<sup>a</sup> Based on a special search in April 1976 in 11 primary health centres.

Of 260 persons who died of chickenpox over a 15-month period, 241 were 20 years of age and older. For many, the immediate cause of death was attributed to "old age" or a chronic or unrelated acute illness, although chickenpox may have been cited as a contributory factor.

It was suggested that the frequency of adult cases related to the dispersed population in Kerala and, until recently, the difficulty of travelling from one village to another. Thus, it was reasoned, many were not exposed to chickenpox until they were adults. The hypothesis was attractive, but other factors must have been involved because adult chickenpox was not such a problem in other, even more isolated, areas of Africa and Asia.

However, cases spread from Gulbarga to 5 other districts in Mysore, to 2 districts in Andhra Pradesh and to at least 1 district in Maharashtra. More than 1400 cases in all were traced to this single district. Although the outbreaks were largely contained in a period of 2 months, fully 6 months elapsed before transmission finally ceased. Most surprising to senior Indian and WHO staff alike were the numbers of health staff who could be mobilized, the rapidity with which a search programme could be organized, and the responsiveness of staff in executing a well-conceived plan. This experience was subsequently replicated in Muzaffarnagar District, Uttar Pradesh (see previous section) and, in May 1973, throughout Orissa State. It

ultimately led to the plan to undertake nation-wide searches for smallpox cases—the essential strategic component of the campaign beginning in the autumn of 1973.

Although transmission was successfully interrupted in Mysore by September 1972, Hyderabad, the capital of Andhra Pradesh, had by then been reinfected; from there the disease spread to 8 other districts. Dr Appa Rao, who was responsible for other programmes in addition to smallpox eradication, was unable to devote sufficient time to the programme and smallpox continued to spread, albeit slowly. Smallpox was reasonably well contained, with the help of Dr Zikmund, until January 1973, when he was forced to leave for Orissa because of outbreaks there

resulting from importations from the Salt Lake Refugee Camp. Smallpox continued to spread in Andhra Pradesh. Between January and June 1973, 924 cases occurred. In view of the size of the population (47 million), the number of cases was not large but, clearly, transmission in Andhra Pradesh and the southern states was not being interrupted as quickly or as easily as had been hoped. The potential for epidemic spread remained, as the Gulbarga experience had shown. The movement of smallpox was too rapid and effective to be contained by the few epidemiologists available.

*West Bengal and the Salt Lake Refugee Camp, 1971*

The densely populated state of West Bengal (population, 46 million), with its crowded capital city of Calcutta (population, 7 million), was a demographic centre of vital importance to smallpox eradication in the eastern states of India. In West Bengal, progress in the control of smallpox appeared to be satisfactory—until December 1971. The number of recorded cases had diminished to only 374 in 1970 and to 217 in 1971, the lowest totals ever reported. The Eastern Province of Pakistan (later Bangladesh) on its eastern border, predominantly Muslim but also Bengali-speaking, had detected its last case in August 1970 (see Chapter 16). Thus, importations of smallpox by travellers who frequently crossed the border were not a threat. However, civil war began in March 1971 in East Pakistan, and during that year an estimated 10 million refugees fled across the border into India. Numerous refugee camps were set up, primarily in West Bengal, Madhya Pradesh and Assam. It was feared that if smallpox were introduced into the camps, devastating epidemics would rapidly develop. On the orders of the National Smallpox Eradication Programme staff, all refugees entering the camps were examined for the presence of smallpox, but no cases were found. As a preventive measure, state officials were requested to ensure that all persons entering the camps were vaccinated. Indian national staff and WHO advisers visited and confirmed that this procedure had been followed in a number of camps, but not in West Bengal, where the state authorities refused to permit national intervention. The largest refugee camp, the Salt Lake Camp near Calcutta, sheltered an estimated 200 000–300 000

persons, and there an international private voluntary organization had been given responsibility for providing health services. For reasons unknown, no vaccination campaign was conducted.

Smallpox was probably introduced into the Salt Lake Camp in November. Many cases were hospitalized within the camp but were diagnosed as chickenpox. The diagnosis of probable smallpox was finally made on 19 January 1972 by an epidemiologist in the USA while viewing a television news documentary made in the camp. The report was relayed rapidly from Atlanta to Geneva to New Delhi. The Director of Health Services of West Bengal categorically denied there were cases, but Dr S. N. Ray, from the National Programme office, flew to Calcutta and, on visiting the camp, found an extensive outbreak. A vaccination programme was begun, but it was too late. On 16 December 1971, one month earlier, the independence of Bangladesh had been proclaimed. By 20 January 1972, an estimated 50 000 refugees had already departed for Bangladesh. The epidemic spread from the camp through West Bengal and from there to the neighbouring states of Orissa and Bihar. West Bengal, which had detected only 217 cases in 1971, reported 4753 in 1972; Bihar reported 1307 cases in 1971 and 4153 in 1972.

The number of cases that occurred in the camp can never be known, but as from 22 January, infected persons among the refugees remaining in the camp were admitted to the Calcutta Infectious Diseases Hospital; admissions continued until the end of February. During this period, the hospital admitted 764 patients, of whom 48% died (Guha Mazumder & Chakraborty, 1973).

West Bengal, which had been comparatively free of smallpox in 1971, became a major epidemic focus in 1972 (Fig. 15.10) and Bangladesh was again reinfected (see Chapter 16).

*The beginning of the "final phase" of the Intensified Smallpox Eradication Programme, November 1972*

By the autumn of 1972, global progress in the Intensified Programme was most encouraging. Only 3 endemic countries remained in the whole of Africa—Ethiopia, Botswana and the Sudan—and in the latter two interruption of transmission appeared imminent. Both South America and Indonesia were smallpox-

free and Afghanistan was almost so. Bangladesh had been reinfected but it had re-established its national programme and Pakistan's programme had been extended to the entire country. India was reporting increasing numbers of cases as epidemic smallpox began moving across the Ganges plain from the west and from Calcutta in the east. However, the extent of the infected areas in India, as well as in other Asian countries, had diminished significantly (Fig. 15.11).

With endemic smallpox so limited geographically and some form of surveillance operating in all areas, it seemed to WHO propitious to encourage a more concentrated effort in the remaining infected areas: the "final phase" of the Intensified Programme. The proposed target was ambitious—to interrupt smallpox transmission during the following 2 smallpox seasons, a period of about 18 months. To encourage the renewed effort, special seminars were convened in

Fig. 15.10. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1972.

September–November in Addis Abeba (mainly for staff in Ethiopia and the Sudan); in Karachi (principally for staff in Afghanistan and Pakistan); and in New Delhi (for staff in Bangladesh, Bhutan, India and Nepal).

In India, despite the success of surveillance–containment measures in southern and western states, many state health officials still persisted in their belief that 100% vaccination was the only way to achieve eradication. With officials from all over India attending the seminar, attention was focused explicitly on the surveillance–containment strategy. The success in Indonesia was a helpful stimulus in encouraging a change in direction, as is illustrated in the following extract from Henderson's opening address:

"Two years ago, in December 1970, a seminar on smallpox eradication was held in this very room. I said at that time that the question was repeatedly asked as to how such major changes [in the smallpox eradication programme] could occur so rapidly when, for years, many endemic countries had been conducting mass vaccination programmes with only limited success. The principal difference between present and past efforts is one component—surveillance. In every country where a concerted effort has been made to investigate promptly and to contain *every* outbreak, smallpox transmission has been interrupted within two years or less. Many of you will recall that at that Seminar the director of the Indonesian programme presented a provocative paper which stated 'a proper surveillance–containment action brought smallpox under control in a short period,

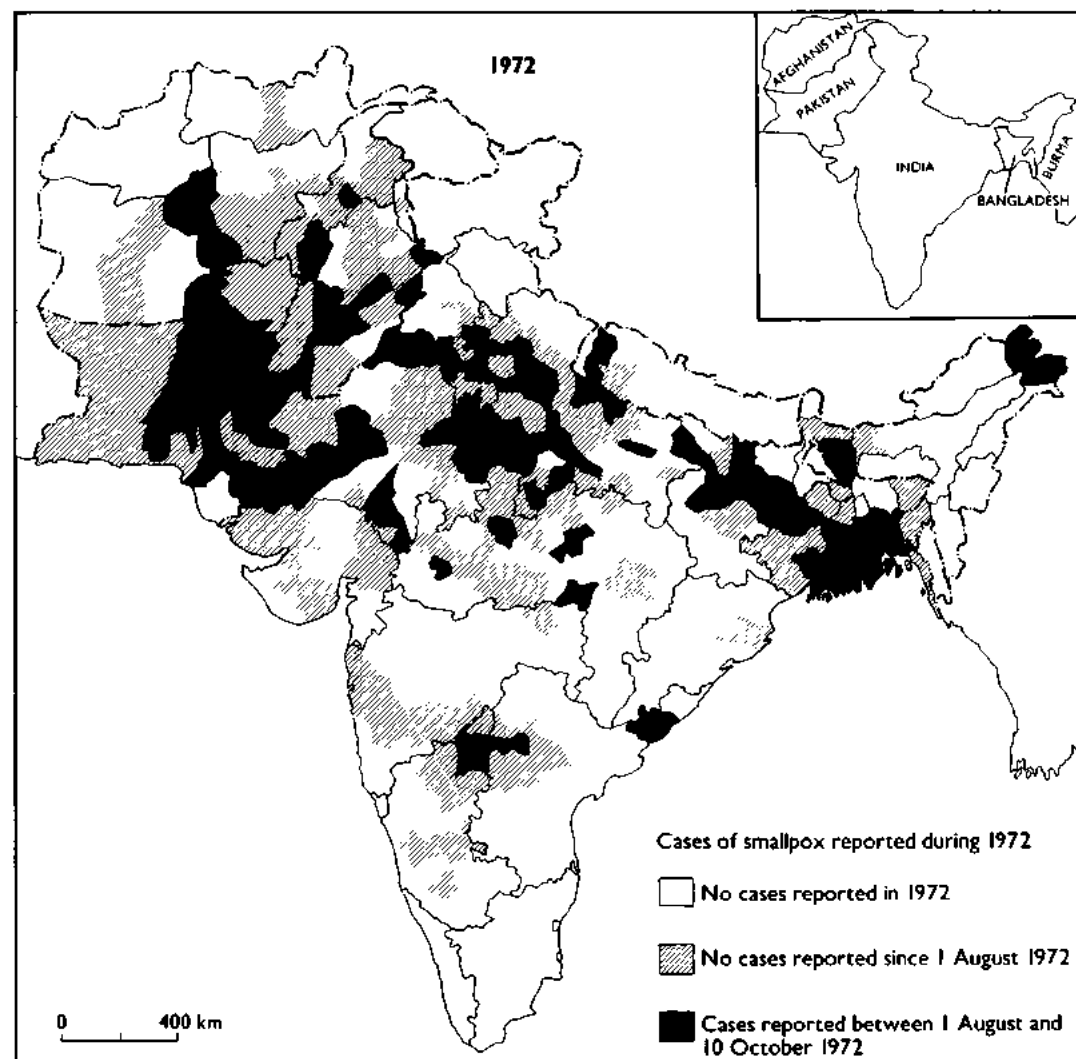

Fig. 15.11. Indian subcontinent and adjacent countries: areas reporting cases of smallpox during 1972 (as of 10 October).

while on the contrary, routine vaccination and mass vaccination campaigns had little effect in interrupting smallpox transmission'. That year, Indonesia reported 10 000 cases of smallpox, only 20% fewer cases than in India. Many at that Seminar took violent exception to the Indonesian director's contention that all available resources should be diverted to surveillance even at the expense of a vaccination campaign. Who was

right? I would ask you to note that the number of cases in Indonesia decreased from 10 000 in 1970 to 2000 in 1971 and to 34 this year. Despite a continuing active search for cases, none have been found in all of Indonesia for over eight months."

State health authorities in India had argued that there were not enough health staff. However, it was noted that, even in countries

**Plate 15.5.** Refugees from East Pakistan, many infected with smallpox, leave the Salt Lake Camp near Calcutta in December 1971 to return to their newly independent country, Bangladesh.

with less well developed health infrastructures, such as Ethiopia, only 80 workers were employed (1 for every 300 000 persons) and in Afghanistan the corresponding ratio was 1 for every 100 000 persons. In India, 1 smallpox vaccinator was available for every 8000–20 000 persons.

The need for surveillance was echoed in the address by the Indian Minister for Health and Family Planning and by Dr P. Diesh, the Additional Director-General of Health Services, who concluded the seminar with the statement: "History tells us that whoever rules the Indo-Gangetic plain rules the country. The battle of smallpox will be fought in the Indo-Gangetic plain, where 70% of the cases are reported now." And this indeed was where the major battle was fought over the following 3 years.

The seminar report concluded with a number of recommendations which stressed surveillance:

1. It is essential to delineate smallpox endemic and non-endemic areas within a state or country. The endemic areas should receive highest priority and the major part of the resources at present available. In the non-endemic areas, an active search for cases should be planned and implemented to ensure their smallpox-free status. Any suspected cases should be dealt with as a national public health emergency.

2. In states where surveillance teams are not yet in existence, state teams should be created by 1 December 1972.

3. The investigation of all outbreaks by the state programme officer or at least by state surveillance teams is essential.

Other recommendations emphasized the importance of containment and the need to trace the source of outbreaks. It was also noted that "the newly introduced reporting system in India should be improved as rapidly as possible". The new system was that previously described, in which primary health centres, districts and states reported weekly all cases of smallpox detected during a given week or reported "nil" if no cases were found.

The central programme office was further strengthened in the autumn of 1972, with the appointment of a senior public health officer to head the programme, Dr R. N. Basu, Assistant Director-General of Health Services (Smallpox), who continued in this position until the conclusion of operations. Dr Basu, who held a more senior rank than Dr Singh, carried greater weight with national and state officials. Dr Diesh, who was effec-

tively second in command to the Director-General of Health Services in the Ministry, also took a special interest in the programme and made a number of visits to the state capitals to meet health ministers and directors of health services in order to encourage greater activity. Visits by an official of this rank were uncommon and implicitly indicated that the government accorded high priority to the smallpox eradication programme. Meanwhile, working relationships between WHO staff and Indian national and state staff had gradually become less formal. Arrangements for WHO staff from the regional office to travel to the field and for state-assigned staff to travel from state to state had become a simple matter of discussion and verbal agreement. This was in marked contrast to the earlier formal relationships which required that, before each trip, a written request should be submitted by the WHO Regional Director to the Ministry of Health and that this request should be considered within the Ministry and eventually a formal reply prepared—a process that often took weeks. With each adviser in possession of a vehicle purchased by WHO and an agreement by WHO to defray all travel costs, a further obstacle to the execution of the programme was removed.

**Plate 15.6.** Rabinder Nath Basu (b. 1928), Assistant Director-General of Health Services, was appointed to direct the National Smallpox Eradication Programme in the autumn of 1972 and continued in this capacity until after the certification of eradication in 1977. He subsequently directed the development of India's Expanded Programme on Immunization and later became the Director of the National Institute of Communicable Diseases.

7 JEFK

**Plate 15.7.** Outbreaks of smallpox occurred among poorly vaccinated pavement dwellers in crowded urban areas. The discovery and containment of such outbreaks were a continuing problem throughout the course of the Intensified Programme.

At the November seminar, goals were fixed in terms of geographical areas within which it was hoped endemic smallpox could be contained by the end of March 1973. For India, it was agreed that by that date the objective would be to eliminate endemic smallpox from all areas except the state of Bihar and 49 districts comprising parts of Uttar Pradesh, Madhya Pradesh and West Bengal.

As early as the end of December 1972, it was evident that the problems once again were greater than had been anticipated. As has been mentioned earlier, major epidemics were discovered in the previously smallpox-free state of Jammu and Kashmir. In Bihar State, health workers went on strike, bringing all work to a standstill. In Uttar Pradesh, then the principal focus of smallpox, eradication staff had been diverted to a cholera vaccination campaign. The new reporting system was an improvement over the old one but, even so, half or more of the states and union territories were consistently up to 5 weeks late in reporting cases.

During 1972, 27 407 cases of smallpox were reported from India, an increase of 69% over the 16 190 cases reported the year before. More complete notification undoubtedly ac-

counted for some of the increase but there was no way of measuring the magnitude. In January 1973, predictions as to the expected incidence of smallpox in 1973 were made by WHO Headquarters staff, in consultation with national staff, on the premise that such predictions served to gauge familiarity with the problems in each area, the rate of progress being made or anticipated and the understanding of the epidemiological situation. It was forecast that 30 700 cases would occur throughout the world, of which 17 000 would be in India. It soon became evident that neither WHO nor Indian staff had comprehended the magnitude of India's smallpox problem.

By the end of March 1973, India had recorded 14 376 cases, of which 29% were outside the established target area. Not only were serious problems present in Bihar, Uttar Pradesh, and Jammu and Kashmir, but it had also become apparent that West Bengal had not done well in controlling the epidemic which had spread from the Salt Lake Camp area. By the end of February, 19 cases imported from Calcutta were detected in Orissa and 30 in Bihar. The estimate of the total number of cases in India projected for 1973 was revised upwards from 17 000 to 35 000

and then to 60 000, a figure which would represent the highest number of cases since 1967. Although reporting had undoubtedly improved, smallpox was far more extensive than had been expected; many still did not subscribe to the new strategy of surveillance and containment. During the spring of 1973, smallpox incidence continued to rise and by the end of June, 49 478 cases had been reported, of which 45 697 (92%) were from the 4 contiguous states in or immediately adjacent to the Gangetic plain—Bihar, Madhya Pradesh, Uttar Pradesh and West Bengal. The total number of cases was almost 3 times greater than the number recorded during the same period in 1972. Comparisons with trends in Pakistan and Bangladesh (*Wkly epidem. rec.*, 1973b) portrayed the unfavourable situation in India (Fig. 15.12).

India was then one of only 4 countries in the world with endemic smallpox, and it accounted for nearly 60% of the world's cases. Politicians and senior health officials alike had become increasingly concerned and had taken a greater interest in the programme. The Twenty-sixth World Health Assembly in May 1973 provided an added stimulus.

During discussions in the Health Assembly regarding the smallpox eradication programme, the delegate from Malaysia bluntly assessed the situation. His observations were summarized as follows (World Health Organization, 1973b):

"... an alarming development in recent months had been that serious smallpox epidemics were raging in two of the endemic countries, despite the fact that WHO was now entering the seventh year of its intensified smallpox eradication programme. Among the reasons for the setback, as given in the *Weekly Epidemiological Record* ... were: lack of staff; inadequately developed surveillance programmes; periodic diversion of smallpox staff to other programmes; delayed and incomplete reporting; and inadequate containment measures. Lack of staff should not be an insurmountable problem; it could be overcome by improved deployment of staff and crash recruitment and training programmes. Nor should it be too difficult to organize and develop surveillance programmes. In view of the vital importance of smallpox eradication, any diverting of staff to other programmes would be premature and ill-advised, and inadequate reporting and containment measures indicated a lack of appreciation of the urgency of the problem. He did not wish to criticize any individual country, but he hoped that the points he had raised would be taken in a constructive spirit.

Fig. 15.12. Bangladesh, India and Pakistan: number of reported cases of smallpox, by month, 1971–1973 (as of 19 June 1973).

"WHO had declared that it was willing to send emergency aid on request ... to any country facing problems in smallpox eradication. He wondered whether the countries now suffering from outbreaks had taken full advantage of that offer ..."

In the World Health Assembly, criticism such as this of another country's health programme was unusual; to India's Director-General of Health Services, it was acutely embarrassing. He returned to India determined to strengthen the programme.

Endemic smallpox in India remained comparatively limited geographically (Fig. 15.13) although the number of cases was large, and it appeared that an intensified programme would require a special mobilization of resources in only a few states of India. With the season of diminished transmission immediately ahead, it was decided to initiate an "epidemic of activity" preceding the usual season of epidemic smallpox.

#### The Intensified Programme in India, June–December 1973

At the end of June 1973, WHO staff from Headquarters and the Regional Office for South-East Asia held meetings with Indian national and state health personnel to devise a new campaign plan whose strategy would be to detect and contain the comparatively

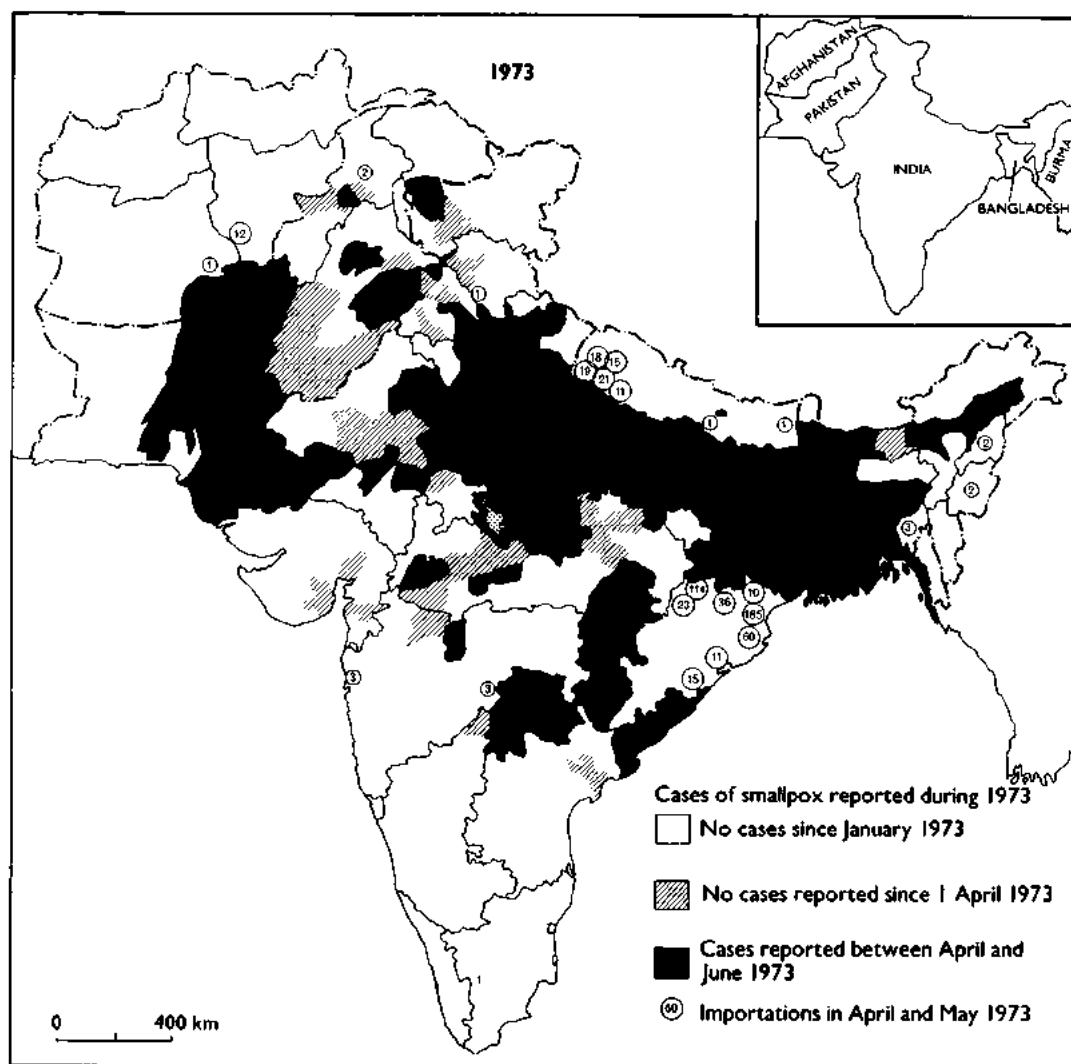

Fig. 15.13. Indian subcontinent and adjacent countries: areas reporting cases of smallpox during 1973 (as of 19 June).

few outbreaks expected to occur during the autumn months of seasonally low incidence. If most of these could be contained by December, it was expected that the remaining foci could also be contained by state and district surveillance teams during the January-June period.

The most highly infected states were Bihar, Uttar Pradesh and West Bengal. There, the deployment of an epidemiologist-adviser and a few surveillance teams for motivating local staff to report cases and to contain outbreaks had clearly failed. A different approach was required. The early detection of cases was of the greatest importance. Once cases were found, a comparatively small number of

containment teams could deal with the outbreaks. Everyone had been impressed by the experiences in Gulbarga District (Mysore) and Muzaffarnagar District (Uttar Pradesh), in which it had proved quite simple to plan and execute a village-by-village programme of case detection which could reach all parts of a district within 1-2 weeks. It was reasoned that if a systematic search of this type could be conducted throughout entire states, in combination with an effective containment programme, it should be possible to contain smallpox quickly. To execute such a search in a state, in a group of states or in the whole of India posed problems of organization and motivation of an entirely

different magnitude from those involved in carrying out the operation in a single district. However, it was apparent that throughout the length and breadth of India a large complement of generally well-trained health staff existed—albeit often poorly supervised and supported. It seemed plausible that an increased number of senior smallpox eradication programme supervisors, following a carefully designed plan, could harness this considerable resource for a concerted effort over a period of a few months. This was the basic strategy decided on, and thus began what was to become one of the most ambitious and intensive national health programmes yet undertaken. Eventually, it would involve more than 130 000 staff who, within a 2-week period, could visit more than 90% of the 120 million households in India.

The principal problem area comprised the states of Bihar, Madhya Pradesh, Uttar Pradesh and West Bengal. Their combined population amounted to 249 million, or about 42% of the entire population of India. It was planned to assign a senior Indian epidemiologist and a counterpart WHO epidemiologist-adviser to assist each state smallpox eradication programme officer in these 4 states. An additional WHO epidemiologist would continue to work in the

neighbouring state of Rajasthan, in which transmission appeared to have been interrupted but which was experiencing many importations. A sixth WHO epidemiologist would be based in Orissa State to assist in the development of search programmes and the investigation of outbreaks in the low-incidence states and union territories geographically close to the 4 highly infected states. He would also assist with any problems in a third group of states which were thought to have interrupted transmission or were expected to do so by September—the smallpox-free group (Fig. 15.14). Additional transport, supplies and equipment were made available by WHO to supplement the already considerable resources deployed by India.

For the 4 highly endemic states, a 3-phase programme was formulated. Phase One, planned for the late summer of 1973, would consist of an active search for outbreaks in municipal areas. It was hoped by this search to find and eliminate urban foci, which often served to sustain smallpox transmission through the summer monsoon season. Because there was insufficient time for preparation, the first phase achieved little except to bring the smallpox eradication activities of most of the autonomous municipal corporations under the supervision of the state smallpox eradication programme office. Phase Two of the programme, from September to December 1973, would consist of state-wide, week-long, village-by-village searches on 3 separate occasions approximately a month apart. Two searches would be conducted in the states with a low incidence, and at least 1 search in the states believed to be smallpox-free. Other health personnel and family-planning workers would be utilized to supplement the work of the smallpox eradication staff. The nature of Phase Three, commencing in January 1974, would depend on the status of smallpox at that time; it was expected that it would consist primarily of a search for cases by surveillance teams and the containment of a few remaining outbreaks.

The government of India and WHO agreed to increase the number of senior supervisory staff for this effort. The government provided an additional senior Indian epidemiologist for each of the 4 priority states. It assigned to the programme Dr M. I. D. Sharma, then the Director of the National Institute of Communicable Diseases; two of his epidemiologists, Dr C. K. Rao and Dr R. R. Arora; and the Assistant

BY COURTESY OF R. S. AGARWALA

**Plate 15.8.** State review meeting in Lucknow, Uttar Pradesh, in 1975. Seated, left to right: M. C. Chaturvedi, Additional Director of Medical and Health Services of Uttar Pradesh; C. K. Rao, member of the Central Appraisal Team; J. M. McGinnis, WHO consultant from the USA; M. I. D. Sharma, Commissioner of Rural Health for India; and N. C. Grasset, smallpox adviser from the WHO Regional Office for South-East Asia. Standing: M. Dutta, member of the Central Appraisal Team.

Director-General for Cholera, Dr Mahendra Dutta. With Dr Basu and Dr Singh of the National Smallpox Eradication Programme, and Dr S. N. Ray, who was responsible for vaccine production, they constituted the Indian component of a group officially termed the "Central Appraisal Team". The WHO component consisted of the intercountry team (formally, the Smallpox Eradication and Epidemiological Advisory Team), Dr Grasset and Ježek, who were joined that summer by Dr William Foege, who had formerly worked in Nigeria and then at the Communicable Disease Center (later called the Centers for Disease Control) in Atlanta, GA, USA, in directing the smallpox eradication effort in western Africa. In January 1974, Dr Lawrence Brilliant, a new member of the WHO smallpox eradication programme staff, became part of the team.

Beginning in June 1973, the group held frequent meetings, preparing, reviewing, and revising drafts of a "Model Operational Guide for Endemic States" and a "Model Operational Guide for Non-endemic States". To implement the programme in the field, 26 special teams were created. Half the teams were headed by Indian epidemiologists recruited by the government from Indian institutes and universities or brought back from retirement. The other half were headed by epidemiologists of other nationalities recruited by WHO. Twenty-two teams were assigned to the high-incidence states (10 to Uttar Pradesh, 2 to West Bengal, 5 to Bihar and 5 to Madhya Pradesh); 2 teams worked in the eastern states; and the remaining 2 in the smallpox-free and low-incidence states in the south.

Eventually, a total of 230 epidemiologists from 31 countries and a comparable number

of Indian epidemiologists would head such teams for periods of 3–24 months each. As many as 90 epidemiologists would be participating at any one time. Each epidemiologist was given 5 days' training before going to the field. Particularly useful for this purpose was a series of slides prepared by WHO illustrating clinical smallpox and 2 case-history studies, one of which dealt with the day-by-day management and investigation of a smallpox outbreak and the other with the management of a district smallpox eradication programme. (The latter eventually found its way into the syllabus of the Harvard School of Business Administration.)

As the autumn campaign began, there were only 26 epidemiologists in the field (Table 15.16). Each epidemiologist in the high-incidence states worked in a zone covering an average of 5–6 districts (approximately 10 million people) and had as his counterpart the division and/or district health officer responsible for the area. The special teams conducted training sessions for district and local staff to explain and organize the searches. In addition, they supervised the implementation and evaluation of surveillance activities and verified the diagnosis when cases were reported. When smallpox was detected, they organized outbreak containment and identified the source of infection.

Additional vehicles were essential and these were quickly obtained through the purchase by WHO of Jeeps manufactured in India. For WHO, this was a departure from a long-standing policy that the country itself should purchase locally produced equipment and supplies. Prompt delivery of the vehicles would have been impossible if traditional procedures had been followed—i.e., the purchase of Indian-made Jeeps by the government or the purchase of foreign-made vehicles by WHO. To have manoeuvred

such a purchase through the complex Indian bureaucracy, even with the highest level of government support, would have taken anything up to a year; the delivery of vehicles from foreign sources was even more protracted at that time. The Indian-made Jeeps, although more susceptible to mechanical failure, were simpler in design and easier to repair. A most important consideration was that spare parts were widely available and there were many mechanics who were familiar with the vehicle. On balance, the Indian Jeeps proved more utilitarian than did imported vehicles.

Each of the epidemiologists was assigned a driver and a paramedical assistant and given a monetary advance (an imprest account) to be used, as necessary, for petrol and vehicle repair, travel allowances and supplies. The funds were accounted for at regular intervals before further advances were made. The disbursement of funds for the discretionary use of the field epidemiologists was also a departure from customary administrative practice, but it was one of the most important steps in facilitating the execution of the programme.

The strategy of the search programme and of the surveillance-containment activities was explained in detail at state-level meetings presided over by state officials and attended by senior officials of the national government and WHO, as well as by state and divisional and/or district health officers. These discussions were followed by similar meetings at the divisional level (for states with a divisional structure) convened by the commissioners of the divisions and attended by chief medical officers of health from the districts and municipal corporations. Meetings were then held at the district level, attended by the district health officers and primary health centre medical officers. Lastly, searchers and

supervisors at each primary health centre were instructed in the specific techniques of search, outbreak containment and reporting. Such meetings at different administrative levels were subsequently conducted before each new search; the experiences of the previous search were evaluated and additional or revised procedures implemented.

To organize the numerous meetings and to develop strategy over the extensive area involved required an extraordinarily intensive effort on the part of the Central Appraisal Team. As an illustration of this endeavour, one may cite the experience of a member of the team who travelled more than 1800 kilometres by car in 5 days, during which he participated in 7 district and regional meetings. To do so necessitated driving all day and through the night; the team member and his driver shared this task, alternately driving and sleeping in the cramped Jeep.

The organizational plan called for one search worker to visit one village or section of a city each day. The hundred or more villages in each primary health centre area were divided up among the staff of 15–20 health

workers. To facilitate supervision, a search schedule determined which worker would be in which village on which date. Each search was planned to be completed within 7–10 days. A supervisor oversaw the work of 4 or 5 workers and was assigned villages to be checked at random.

The searchers were instructed to show the WHO smallpox recognition card (see Chapter 10, Plate 10.11) and to inquire about any suspected cases that had occurred during the preceding 2 months. All village leaders and watchmen were to be contacted, as well as schoolteachers and their pupils, and persons congregating in tea-shops and market areas. Two or 3 houses in each of 4 parts of a village and the section of a village or town in which the poorest families lived were also to be visited. When the teams travelled from village to village, they were instructed to stop at brick kilns, bus stands, migrant camps and festivals to solicit reports of possible cases of smallpox.

Suspected cases were to be notified immediately to the primary health centre physicians, who were asked to verify the diag-

nosis. In addition to the assessment of work by the supervisors, each primary health centre medical officer was expected independently to assess one village or urban area assigned to each supervisor; each district-level supervisor was expected to visit one village, one school and one market in each primary health centre area; and each state surveillance team was expected to check 100 villages, 10 markets and 30 schools after each search. Areas selected for assessment were the least accessible villages and those most distant from the primary health centre. It was assumed that if the work was well done in the more distant and difficult areas, it was likely to be satisfactory in the areas easy of access. Radio, press, and other media were utilized to inform the public where to report cases of smallpox.

The first searches in the highly endemic states began in September. With such large populations and with so many health staff involved, the logistic requirements were formidable, as will be appreciated from the following inventory of material supplied to West Bengal for its first search: 100 copies of the Operational Guide; 10 000 smallpox recognition cards and 3000 large recognition cards; 100 copies of each district map to be used to plan search workers' schedules; 3000 copies of the searchers' village-by-village schedules; 16 000 copies of forms for recording the results of the village

visit; 400 copies of forms for listing outbreaks; and 3000 copies of the weekly reporting form to be dispatched from the primary health centres to the district. For a country-wide search, it was calculated that 8 tonnes of forms would be necessary.

Because of floods, only 9 out of 16 districts in West Bengal could be reached during the September search; but only 75 cases of smallpox were detected. It was uncertain whether the search had been good and the few cases that existed had been found, or whether it had been poor and many cases had been missed. However, a more extensive search conducted throughout the state in early October identified only 143 infected villages among West Bengal's 38 000 villages and 137 towns. Moreover, Calcutta, which many had feared might harbour extensive foci, had far fewer cases than had been expected.

The encouraging reports from West Bengal were quickly followed by alarming—almost unbelievable—reports from Uttar Pradesh and Bihar. During the week preceding the search, only 354 cases in 21 districts had been reported in Uttar Pradesh and only 134 cases in 8 districts in Bihar. However, the 1-week October search revealed 1525 outbreaks with 5989 cases in Uttar Pradesh and 614 outbreaks with 3826 cases in Bihar (Fig. 15.15; Table 15.17). It should be noted, however, that outbreaks occurred in only

	Dec.		51 (0.1)	2	53	215

1.3% of all villages in Uttar Pradesh and in only 0.9% in Bihar. However, smallpox was found in 42 out of the 293 municipalities in Uttar Pradesh, in 13 out of 161 in Bihar, and in almost all districts of both states.

The staff had cause for alarm because, in October, smallpox incidence was at a seasonal low. Moreover, the percentage of villages then infected was equivalent to the percentage infected *at any time* during the course of an entire year in the studies by Dr D. B. Thomas and his colleagues in Sheikhpura District in Pakistan (Thomas et al., 1972; see Chapter 14). Until this time, Sheikhpura District had been considered to be the prototype of a district with an unusually high incidence of smallpox in the generally well-vaccinated Indian subcontinent.

Despite the extensive planning and training, assessment revealed that many villages, indeed entire areas, had not been searched, and thus even the high figures recorded understated the problem. With smallpox present throughout both states and in many urban areas, it was apparent that when transmission rates increased, a major epidemic would be possible. In neither state were the health services functioning well and a 3-month period of intensive training and supervision provided little time in which to improve the performance.

The November and December searches were more thorough than the October search. Nevertheless, the number of infected villages which were discovered decreased in both states—more sharply in Uttar Pradesh, suggesting that the new strategy was having an impact. In Madhya Pradesh, geographically India's largest state, the first search was delayed until November because of floods. The results there were highly encouraging. Only 170 outbreaks were found in November and only 53 in December.

Searches in 8 "low-incidence" states revealed only 4 with outbreaks and, during 2 separate searches, fewer than 200 cases were discovered in each (Table 15.18).

Of 10 states which had been expected to be free of smallpox by September, only Andhra Pradesh was found to have had outbreaks, and, in all, only 197 cases were discovered (Table 15.19).

As 1973 ended, it was apparent that large areas of India had remained free of smallpox (Fig. 15.16), and the search programme had confirmed this. In December only 6 states recorded 100 or more cases, and 2 of them—Bihar and Uttar Pradesh—accounted for 84% of the total (Table 15.20; Fig. 15.17). Although the total number of cases recorded in India was 88 114, the highest since 1958, reporting was far more complete than it had ever been.

The autumn campaign had shown that it was possible to mobilize health resources effectively throughout entire states to search for cases and to contain outbreaks. However, with smallpox still widely prevalent in the 4 central states and the period of high transmission again beginning, it was clear that Phase Two of the campaign had to be extended into 1974.

In early January 1974, Henderson had meetings in New Delhi with Indian and WHO staff to assess possible strategies and needs for the coming months. The situation was critical. If the intensified search campaign was to continue, a commitment of additional funds was urgent. Funds earmarked for India in the WHO regular budget were sufficient to cover the campaign activities for 2–3 more months at most. To obtain additional money from WHO was a problem. WHO's budget for smallpox eradication had remained at a constant level since 1967. The funds had been proportionately

allocated to each of WHO's regional offices in 1967 and the proportions had not changed thereafter. With the certification of eradication in the Americas in 1972, it had been requested that the 1973 allocation for that region should be transferred to the South-East Asia Region. However, the proposal was turned down. Within the South-East Asia Region, some diversion of funds from Indonesia, now free of smallpox, was possible but the amount was not great. Meanwhile, repeated appeals to governments for support had brought generous donations of vaccine but little cash. A further emergency appeal was considered but thought to be futile because governments could seldom respond to such requests in less than several months to a year. Although the programme in India had achieved a momentum which offered hope of success, little could be done without additional resources and there appeared to be no solution forthcoming. Henderson returned to Geneva to consult the newly elected Director-General, Dr Halfdan Mahler. Later that week the WHO Executive Board was to meet. On the agenda was the question of how to use US\$900 000 allocated to China, a new Member State of WHO, which had declined to accept WHO funds provisionally allotted for the support of its health programmes. The Director-General agreed immediately that a cable could be sent

to India indicating that these funds would be used for its smallpox eradication programme, a decision later endorsed by the Executive Board. Another emergency in an apparently never-ending series of financial crises in the programme had been averted.

### The Darkest Months of the Programme, January-June 1974

In January 1974 optimism prevailed. Funds were available to continue the programme, case notification was far more complete than ever before, and the search programmes were showing steady improvement in all states. In Bihar, in which the greatest numbers of cases were being recorded and the health services were the least adequate, the programme office reported that 50% more villages had been visited during the third search, in December 1973, than during the first in October. Despite a more extensive search and despite seasonally higher transmission rates, fewer villages with new outbreaks had been found.

The results in Uttar Pradesh had been even better, with the number of newly found outbreaks declining from 1525 in October to 331 in December. Progress in West Bengal was no less encouraging. There, Arita had introduced a new system to document progress in the programme. From October

**Plate 15.10.** Implementing the search programme required extensive field work by national and international staff. **A:** Ram Rakha Arora (b. 1925), an Indian member of the Central Appraisal Team in West Bengal. **B:** Left: Lawrence Brent Brilliant (b. 1944), an epidemiologist from the WHO Regional Office for South-East Asia; right: Anatolij N. Slepushkin (b. 1929), an epidemiologist from the Smallpox Eradication unit at WHO Headquarters.

1973, each newly discovered outbreak was added to a master list as an "active outbreak" and not removed from the list until 4 weeks had elapsed since the last case. At the end of December, there were only 124 active outbreaks in the whole of that populous state. In Madhya Pradesh, the last of the 4 key central states, a search conducted during 7-12 January 1974 revealed only 49 new outbreaks, two-thirds of which consisted of 3 cases or

less. Of 5000 outbreaks discovered in these 4 states between October and December, it was estimated that not more than 1700 were still active. In the other states, the number of reported cases—many of them resulting from importations—remained low. Meanwhile, Bangladesh reported that only 172 of its villages were infected; in Nepal, virtually all outbreaks were said to have resulted from importations.

Fig. 15.16. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1973.

### The Dedication of the Smallpox Programme Staff

The commitment and determination of staff who worked in the programme were extraordinary and indeed might well be the subject of a separate book. The meeting in New Delhi on 1 January 1974 of the Indian and WHO Central Appraisal Team and Henderson provides an illustration. All members of the team had been working a 7-day-week for nearly 4 months, travelling to some of the country's most remote and inhospitable areas in a frantic effort to motivate the army of health workers to contain the vastly larger number of outbreaks than anyone had foreseen. All had lost weight and were exhausted, one person had incapacitating renal colic, a second a painful facial herpes zoster infection, a third a serious fungus infection of the foot (which eventually required surgery) and a fourth atypical pneumonia with high fever and pleuritic pain. The only question asked at the meeting was how to find additional resources to sustain the momentum. When Henderson expressed scepticism of their own ability to work, let alone to continue the schedule proposed even if given the needed resources, the reply was simply: "We've considered the question and have decided that things can't get worse; therefore they must get better".

Exemplifying this determination in the field was a 50-year-old Indian professor of social and preventive medicine, Dr T. P. Jain, who was assigned as an epidemiologist in a flood-stricken area of Assam. Investigation and containment of many of the outbreaks required wading from house to house in areas in which leeches were legion and snakes a problem. A devout member of the Jain religion, he had requested a week's leave to attend ceremonies in another state commemorating the 2500th birthday of Mahavira, founder of the religion, a long-anticipated and sacred event. Another epidemiologist, arriving in the area to check the existing outbreaks in Jain's absence, found him waist-deep in water trudging from house to house, unwilling to leave for even a day so long as smallpox persisted in his area.

The commitment of the government to the programme was demonstrated early in 1974, when Dr Sharma was promoted to the position of Commissioner of Rural Health while retaining responsibility for smallpox eradication. Dr Sharma was widely known and respected among professional health staff and politicians alike for his expertise in the field of communicable diseases and for his executive ability. He had the full support of the Minister of Health and Family Planning, Dr Karan Singh. His commitment to the surveillance-containment strategy was total, and this he communicated to national and state officials on frequent visits to the field. It was important that he did so because the Director-General of Health Services, to whom he was subordinate, adhered to the traditional view that only a thorough mass vaccination campaign could succeed in eradicating smallpox, a view he expressed on frequent occasions. In part because of this contradictory advice, state officials in Bihar and occasionally in Uttar Pradesh were to call periodically for the suspension of search and containment activities in favour of total mobilization for a mass campaign to vacci-

nate everyone in the state. The mass vaccination approach was more easily understood and although it had been demonstrably unsuccessful in the past, there was the belief that if the health personnel were *really* properly organized and motivated the objective of 100% vaccination could be achieved. Dr Sharma's appointment ensured that the basic surveillance-containment strategy would be sustained.

A summary statement appearing in a WHO South-East Asia Regional Smallpox Surveillance Report (4 February 1974, unpublished) is indicative of the optimism prevailing at the beginning of 1974:

"The tremendous increase in smallpox activities in the region since October 1973 has had its impact. Smallpox is diminishing in many areas at a time when it traditionally increases ... proving that smallpox transmission can be interrupted even at the height of the smallpox season. Within a few weeks a decrease in the transmission of smallpox can be expected ... If programme activities can be maintained or increased, most areas in India and Bangladesh could interrupt transmission before the monsoons."

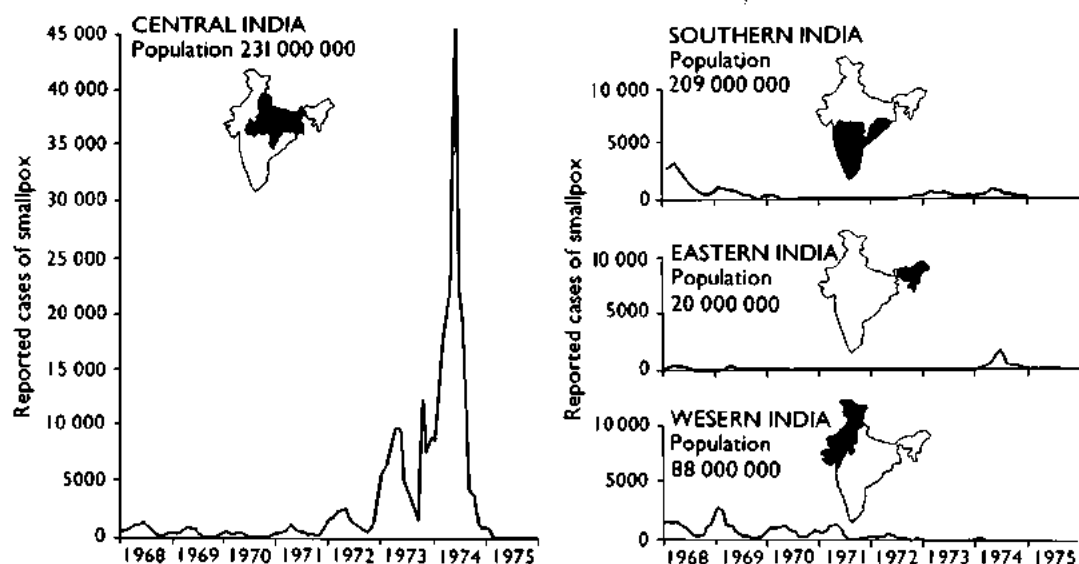

Fig. 15.17. India: number of reported cases of smallpox, by region, 1968–1975. (Population data for 1971 from Basu et al., 1979.)

BY COURTESY OF R. S. AGARWALA, 1974

**Plate 15.11.** Mudi Inder Dev Sharma (b. 1919), the Commissioner of Rural Health for India, vigorously and enthusiastically supported the programme from early in 1974 through extensive travel and personal inspiration. He is using the WHO smallpox recognition card to ask villagers in Uttar Pradesh State about possible cases of smallpox.

It was to be the last optimistic statement for many months.

In February 1974, the fourth search was conducted in Bihar. It revealed 1170 new outbreaks in villages and 18 in urban areas, almost 3 times the number (405) found in December, and more than twice as many cases

as in January—10 697 as against 4816 (Table 15.21). The most seriously affected areas were the eastern districts. From here, smallpox began to spread to West Bengal (65 importations by mid-February) and to Nepal (11 importations).

Additional Indian and WHO epidemiologists were hurriedly recruited and assigned to Bihar. The fifth search (11–16 March) revealed 2374 new outbreaks, double the number found in February: more than 7000 cases were recorded during the search period (Fig. 15.18). By the end of the fifth search, there were 3682 active outbreaks in the state. Containment policies at this time called for the vaccination of residents only in the 20–30 houses adjacent to infected households. Even so, there were too few surveillance and containment teams to be able to visit more than a small proportion of the outbreaks, which were detected in many areas, and even the minimal containment measures were poorly executed. Desperate for additional help to supervise the search and containment programme, senior programme staff decided to recruit recent medical school graduates and, after a special training programme in New Delhi, 40 “junior doctors” were assigned to field work in Bihar. Eventually 140 were to participate (Jha & Achari, 1975).

Epidemic smallpox in Bihar was a problem of formidable proportions, and the occurrence of one natural or man-made calamity

<sup>a</sup> Population estimates by states are based on United Nations (1985) data for all of India proportionately allocated by state on the basis of the 1971 census.

<sup>b</sup> No cases were reported during this period in the union territories of Andaman and Nicobar Islands, Dadra and Nagar Haveli, Goa, Daman and Diu, Lakshadweep, and Pondicherry.

after another further hampered the eradication effort. Indian Airlines workers went on an extended strike, making it difficult to ship vaccine and for senior personnel to travel. The railways began to be extensively used until railway workers likewise went on strike. Meanwhile, the international oil crisis had developed and, in April, petrol costs in India doubled and shortages occurred. Drought in southern Bihar, sufficiently severe to require international assistance, resulted in the migration of large populations of refugees seeking food and spreading smallpox. This was soon followed by the most severe floods in a decade in northern Bihar and even more refugees fleeing in search of food and refuge. Civil disorder and political disturbances began to occur throughout Bihar and, over large areas, government authorities were totally occupied with maintaining law and order. Throughout this period, heroic efforts were made to ensure an adequate flow of supplies and to stockpile materials such as

vaccine and reporting forms in anticipation of expected shortages; however, most supplies were barely adequate to meet the current needs.

That the programme in Bihar functioned at all was remarkable and for this due credit must go to its Smallpox Programme Director, Dr A. G. Achari, a conscientious and tireless worker who, with the officers of the Central Appraisal Team, Dr Foege and Dr Dutta, sought valiantly to mobilize a lethargic health staff and to sustain morale among the Indian and WHO epidemiologists, who were overwhelmed by the explosive spread of smallpox.

When it seemed that little else could possibly go wrong, the health workers in Bihar threatened to go on strike. Dr Achari, Dr Dutta and Dr Foege sought desperately to develop a contingency plan but with little support. The observation of one district health officer was characteristic of the attitude of some supervisory health staff: "If we

Fig. 15.18. Bihar State: number of reported cases of smallpox, by week, showing results of special searches, January–May 1974.

Fig. 15.19. Bihar State: number of active outbreaks of smallpox, by district, as of 5 May 1974.

don't have a strike, we don't need a contingency plan; if we do have a strike, it is no longer my responsibility."

The sixth search in Bihar (29 April–4 May) recorded 2658 additional outbreaks—the number of active outbreaks increasing to 4921. More than 7% of all villages and municipal areas in the state were infected, the most heavily afflicted being in the north-east (Fig. 15.19), where, in 3 districts, 25% of all villages were infected.

India's Director-General of Health Services, still an advocate of mass vaccination, became increasingly alarmed and advised Bihar's Minister of Health to withdraw staff from the infected areas and to begin mass vaccination campaigns in the areas still free of smallpox to prevent them from becoming infected. Dr Sharma, learning of this only after the minister in Bihar had begun to take action, protested direct to India's Minister of Health and Family Planning, Dr Karan Singh, and together they flew to Bihar to intercede. The Bihar minister rescinded his order. In an epidemic as extensive as that occurring in Bihar, some of the Indian and WHO programme epidemiologists began to speculate that Bihar might represent a special case in which the now well-tested surveil-

lance and containment strategy might not be applicable.

Throughout May and into early June, the epidemic continued to intensify. With daytime temperatures normally exceeding 40 °C, field work became ever more difficult, morale began to deteriorate and, again, the question of a return to state-wide mass vaccination arose. The minister was more resolved than before and, in the June meeting of state and district programme officers, strongly advocated this approach. Senior programme staff argued in vain, until an Indian physician, working in one of the districts, pointed out in a deferential manner that he had grown up in a village and there, when a house was on fire, they put water on that house and not on all houses in the village. The minister reluctantly agreed to defer a mass vaccination campaign for one more month but only on the understanding that if no apparent progress had been made by then, mass vaccination would be initiated. Senior staff hoped that, even if containment were less than optimum, the seasonal decrease in transmission would partially stem the epidemic and so preserve what they believed to be the only possible effective strategy—surveillance and containment.

WHO/C. HENRIQUET, 1975

**Plate 15.12.** Karan Singh, Minister of Health and Family Planning of India from 1973 to 1977, provided strong political support for the programme and for the surveillance-containment strategy.

In the other states of India, the situation was better than in Bihar but not so good as had been expected in February. Uttar Pradesh was the next most heavily infected state. The numbers of reported cases and outbreaks had risen steadily since January, although less precipitously than in Bihar. A peak of 1905 active outbreaks was reached in May, with 8337 cases reported that month. Outbreaks were reported from 442 (51%) of the state's 875 primary health centres and in 47 of its 55 districts (Srivastava & Agarwala, 1975). However, 82% of the outbreaks occurred in only 15 districts, primarily in eastern Uttar Pradesh, where their large number precluded the taking of effective containment measures. Elsewhere in the state, with the support of the Director of Medical and Health Services and Family Planning, Dr G. P. Srivastava, the health staff had begun to function well.

In West Bengal, the number of active outbreaks increased steadily, from 124 in December to 556 following the seventh search in mid-April. However, more than 75% of the outbreaks took place in only 5 of the state's 16 districts, and here village volunteers began to be recruited and trained for containment operations, an effective practice later adopted in other states. The increase in the number of outbreaks in West Bengal was largely accounted for by importations, mostly from Bihar. Between January

and May, programme staff documented 386 imported outbreaks, and others occurred as a result of spread from these importations.

Importations, principally from Bihar, Uttar Pradesh and West Bengal, accounted for an increase in the number of cases in Madhya Pradesh, Maharashtra and Orissa. Each state worked diligently and effectively to discover and contain the outbreaks as rapidly as possible, but by May, both the smallpox eradication staff and the general health service personnel were reaching a critical point of fatigue and frustration. Meanwhile, the eastern states, hitherto all but free of smallpox, experienced a sharp increase in the number of cases, resulting from importations from Bangladesh, Bihar and Uttar Pradesh. This was cause for additional alarm because, in the eastern states, health services were generally less extensive and not much better organized than those in Bihar. Although they were not populous states, road and rail services were poor and both search and containment activities were difficult to organize and to execute.

The unexpected and explosive epidemic of smallpox in Bihar and its spread to other states had required the mobilization of far more Indian and WHO epidemiologists (see Table 15.16) than had been foreseen and had necessitated the emergency purchase of more vehicles and supplies of all types than had been planned. By April, funds to support the smallpox programme were again at a low level. Requests were made to numerous governments for additional finances; few showed any interest and no country indicated it was in a position to act quickly in answering an appeal. Privately, many expressed scepticism about the programme's prospects of success. The reaction was not surprising in view of the fact that the number of cases of smallpox recorded in India in the spring of 1974 was the largest for nearly two decades. WHO's frequent appeals in the past for funds to bolster its malaria eradication campaign, and the continuing setbacks in that programme despite infusions of ever larger sums of money, were well remembered. Once again, the programme approached a critical point, but, unexpectedly, substantial help materialized from a new source, the Swedish International Development Authority (SIDA). In a casual conversation with the Personnel Officer of the WHO Regional Office for South East Asia—an official of Swedish nationality—Dr Grasset learned

1980

**Plate 15.13.** Jarl E. Tranaeus (b. 1923), Head of the Development Co-operation Office of the Swedish Embassy in New Delhi from 1973 to 1978, persuaded Swedish authorities and the Indian government's Planning Commission of the need for substantial additional assistance to the smallpox eradication programme at a crucial moment.

that SIDA planned to examine alternative uses for Swedish funds which had become available because of the cancellation of another project in India. Discussions promptly followed with Mr J. Tranaeus, at the Swedish Embassy in New Delhi. Convinced, as few others were, that an effective and well-directed campaign was in progress whatever the smallpox incidence might suggest, he persuaded the Planning Commission of the government of India, as well as his superiors in Stockholm, of the merits of the programme. Within a few weeks, a memorandum of agreement had been signed on behalf of the governments of India and Sweden which made available to

WHO US\$2.8 million in support of the smallpox programme. With Mr Tranaeus's continuing enthusiastic interest, SIDA was eventually to provide US\$10 million to the programme. The government of India also increased its own central allocation of funds. For 1974, a sum of US\$13 million was made available for field operations.

Time was required to effect the necessary transfer of funds, but the Division of Budget and Finance in WHO Headquarters readily agreed to permit funds to be obligated even though they were not yet in hand. Meanwhile, the administrative staff in the WHO regional office were experiencing difficulties, because of the substantial expansion in the number of personnel in the programme receiving a stipend from WHO, the larger numbers of imprest accounts to be handled and the need to procure a greater volume of supplies (Table 15.22). It was essential that additional personnel should be recruited and that budget and finance operations should be established for the programme. The Center for Disease Control (formerly the Communicable Disease Center) in Atlanta, which was already providing many field epidemiologists, responded to this need by sending its most capable senior administrative staff to help to bring some order into an increasingly chaotic administrative situation. Beginning with the Center's Deputy Director, Mr William Watson, an exceptionally imaginative group of administrators worked tirelessly with the group of no less talented WHO administrative staff to provide essential services in support of the field staff.

Although the smallpox epidemic was featured more often and with greater prominence in Indian newspapers, little was known of the problem outside the country. However, in May 1974, the epidemic became international news. On 18 May 1974, India tested its first atomic device in an underground explosion in Rajasthan. At that time, the smallpox epidemic was at its height, more than 11 000 cases being reported in a single

**Table 15.22.** India: principal supplies and items of equipment provided by WHO, 1970-1976<sup>a</sup>

Item	1970	1971	1972	1973	1974	1975	1976	Total

<sup>a</sup> Between 1972 and 1976, it is estimated that WHO, in addition, arranged to print and distribute the following material: approximately 31 million forms for use in reporting and in search and containment operations; 500 000 booklets for use in outbreaks and in market searches; 400 000 posters; 1 million smallpox recognition cards; and 500 000 other guides and miscellaneous publications.

week. International news reporters who had flown to India to cover the atomic test arrived just as the smallpox epidemic hit the headlines in the local press; international media coverage of both events was extensive. Programme staff repeatedly explained that more complete reporting accounted in major part for what appeared to be the largest epidemic for many years, but scepticism was prevalent and understandable.

Although the problem in Bihar was serious, the eradication programme throughout India was steadily improving and gaining momentum. Week-long village-by-village searches were being performed each month throughout the high-incidence states and less frequently in the others (Table 15.23). The number of those engaged in the searches was increasing (Table 15.24).

As serious and frustrating as the situation appeared, yet another disaster aggravated it—the Jamshedpur epidemic in Bihar State. Its discovery resulted from investigations in

Madhya Pradesh. Special efforts had been made to interrupt transmission in Madhya Pradesh. It was one of the 4 central states considered to be of highest priority, and was geographically the largest state in India, with a population of 46 million. Most of the outbreaks which had been discovered during the autumn searches were in the northern and eastern districts of the state, bordering on Bihar and Uttar Pradesh. The December 1973 search had revealed only 215 cases and 53 new outbreaks. By the beginning of March 1974, and after 5 monthly searches of its 10 million households, smallpox appeared to be present in only a single, geographically limited focus, in a tribal area and one of the least developed parts of the state.

In late March 1974, however, reports of smallpox outbreaks began to arrive from many areas of Madhya Pradesh which had been considered to be smallpox-free. Investigations revealed these to be the result of recent importations from the neighbouring state of Bihar. The source of infection of many was traced to an industrial complex in southern Bihar: Jamshedpur in Singhbhum District. *Adinassis* (tribal people) often travelled 300–800 kilometres to Jamshedpur from their homes in Madhya Pradesh in search of seasonal employment. If they became ill with fever, they returned to their native villages, where many subsequently developed rash and spread smallpox to others.

Dr Brilliant was dispatched to Jamshedpur in late April to assess the situation. He found a major problem of unexpected magnitude.

#### *The epidemic in Jamshedpur, Singhbhum District, Bihar*

The Jamshedpur industrial complex is one of India's most important steel-producing areas, its prosperity contrasting sharply with economically depressed neighbouring areas of southern Bihar, eastern Madhya Pradesh

BY COURTESY OF TATA INDUSTRIES

**Plate 15.14.** The office of Tata Industries, Jamshedpur, became the smallpox eradication headquarters for Chotanagpur Division, Bihar State.

and northern Orissa. As such, it attracted numerous seasonal workers, beggars and transients.

The special investigation began in early May. The District Medical Officer of Singhbhum disclosed that during the preceding 6 weeks, he had received 125 notifications of outbreaks in other districts of Bihar and in other states which were suspected of having originated in his district, and that 12–15 notifications were then being received daily. Little action had been taken, the government health structure in this district being poor. In addition to 27 primary health centres that reported to him, all of which were then known to have smallpox cases, there were 15 autonomous and separately administered health units in Jamshedpur (population, 800 000). The health units included small company towns, corporations, large colonies of railway employees and others. No one was charged with the task of reporting cases among the large migrant population, and the railways denied all responsibility for the reporting of cases from the areas they administered. Half the health units were found still to be using rotary lancets.

At the industrial complex, a group of heavy industries of the Tata group, officials professed ignorance of the problem but immediately agreed to provide help in a search of the city and of 1760 villages within a 45-kilometre radius. In a search that took place in mid-May, 50 physicians, 200 paramedical supervisors and 900 searchers discovered 1479 cases in the city and 726 cases in the 456 villages found to be infected (Basu et al., 1979). An intensive programme of containment and case detection was immediately undertaken. This involved, in addition to government and WHO health staff, personnel and transport provided by 7 of the Tata industries as well as voluntary organizations, including the Rotary Club, the Lions Club, the Bihar Flying Club, the local blood bank and the All-India Women's Council (Bharucha, 1975). All bridges and major roads were barricaded and no one was permitted to pass unless vaccinated. A special programme dealt with railway travellers, especially third-class passengers, of whom perhaps one-third travelled without tickets. Trains were diverted to special platforms, which permitted all passengers to be checked

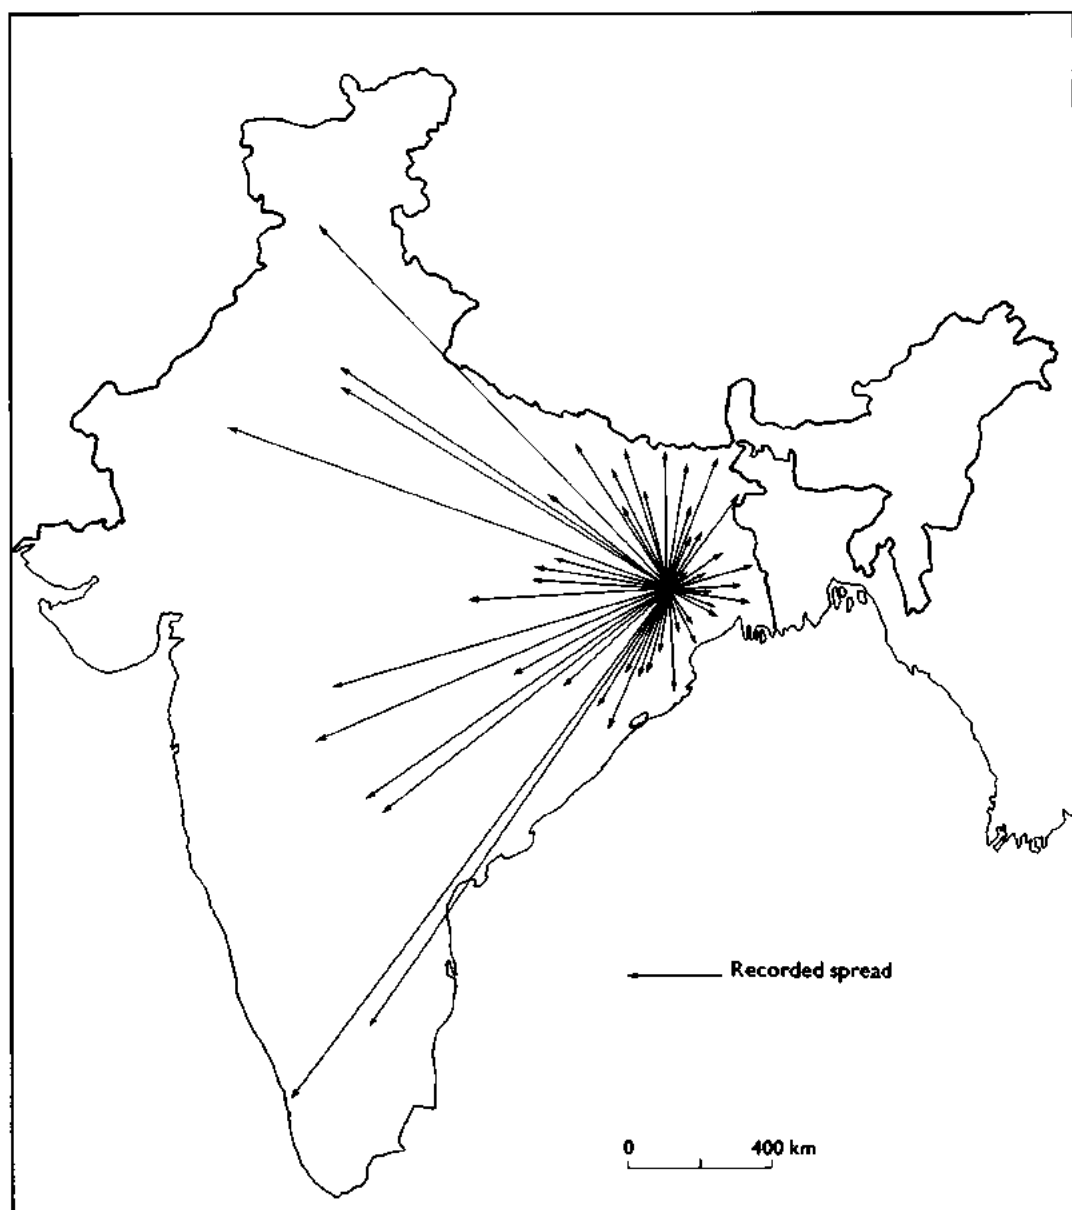

Fig. 15.20. Spread of smallpox from the Jamshedpur urban industrial complex to the rest of India, 1974.

when boarding or leaving a train. Check-points were established at bus stations, and employers ensured that workers and their families were vaccinated. Meanwhile, the containment of all known outbreaks began, an effort which in fact necessitated house-to-house vaccination of the entire urban complex and most of the surrounding villages.

Two months were required to bring the epidemic under control. Meanwhile, 300 outbreaks and at least 2000 cases occurred in 11 states of India and in Nepal as a result of

travel from Jamshedpur (Fig. 15.20). The area most affected was Bilaspur District (Madhya Pradesh), with 484 cases in 72 villages.

#### A Redoubled Effort, June–December 1974

Early June 1974 was the psychological low point of the Indian smallpox eradication programme, if not of the global Intensified Programme itself. A 9-month intensive campaign had been conducted throughout India

Fig. 15.21. India: number of districts reporting cases of smallpox, by month, 1971-1975.

with senior staff and numerous field staff working 7 days a week. Despite the large expenditure of money and effort to date, and despite what appeared to be an increasingly successful effort in surveillance and containment activities, there were 8664 known outbreaks. Moreover, up to the end of May, India had already recorded 116 188 cases, a number greater than that reported for the entire world during any of the preceding 6 years of the Intensified Programme. Cases were reported in May from nearly one-third of the districts in India, of which 80 reported 50 cases or more (Fig. 15.21). Many areas of India remained free of smallpox or had only a few outbreaks resulting from importations (Fig. 15.22), but the epidemic wave then surging through Bihar seemed to be moving both east and south. It was clear that the efforts made so far in Bihar had been inadequate to contain smallpox, and the states which appeared to be the next candidates for epidemic smallpox—Orissa to the south and the states to the east—had health services which were not much better in quality than those in Bihar.

During June, with the beginning of the monsoon period, smallpox transmission normally declined in India and the number of outbreaks diminished. However, with the disease so widely seeded throughout Bihar and adjacent areas, it was clear that unless a concerted effort were made to contain the outbreaks during the summer, smallpox would remain widely disseminated at the commencement of the next season and the

experience of the spring of 1974 would be repeated. Activities of all types usually diminish in India during the summer months—the hottest, the most humid and the most difficult months of the year in which to work. A staff which had toiled to the point of exhaustion between September and May would have to mount one more effort.

On 17 June 1974, the Central Appraisal Team met the Secretary of Health and the Director-General of Health Services to discuss an emergency programme for the whole of India, but especially for Bihar. It was decided to increase the number of special epidemiologists from the 50 who were in the field at the time to more than 100. WHO would initially provide 12 additional international epidemiologists, and 6 non-medical surveillance officers; the government of India would attempt to recruit 40 epidemiologists. If that proved impossible, WHO would try to obtain the services of more international epidemiologists.

Six central-level surveillance teams would be established which would respond to emergency smallpox problems as they developed. State surveillance teams, hitherto restricted in travel to the state in which they were assigned, would be directed to cross state borders whenever necessary to seek the source of infection of outbreaks.

Three hundred additional containment teams would be recruited, each to be headed by recent Indian medical graduates. A further 375 Jeeps would be purchased or hired. To

fund these activities, SIDA offered additional financial assistance, which was rapidly made available.

It was recognized that special efforts would be required in Bihar. Following consultations between the staff of the WHO regional office, the Governor and the State Health Minister, the Chief Secretary of the State of Bihar sent a special letter to all district magistrates, informing them that as from the

end of June they and the block development officers would assume responsibility for the conduct and organization of the campaign in their districts. Dr Achari would continue in his role as State Smallpox Eradication Programme officer but more effective senior administrative staff would replace the health service staff in bearing primary responsibility for the programme.

The president of Tata Industries was

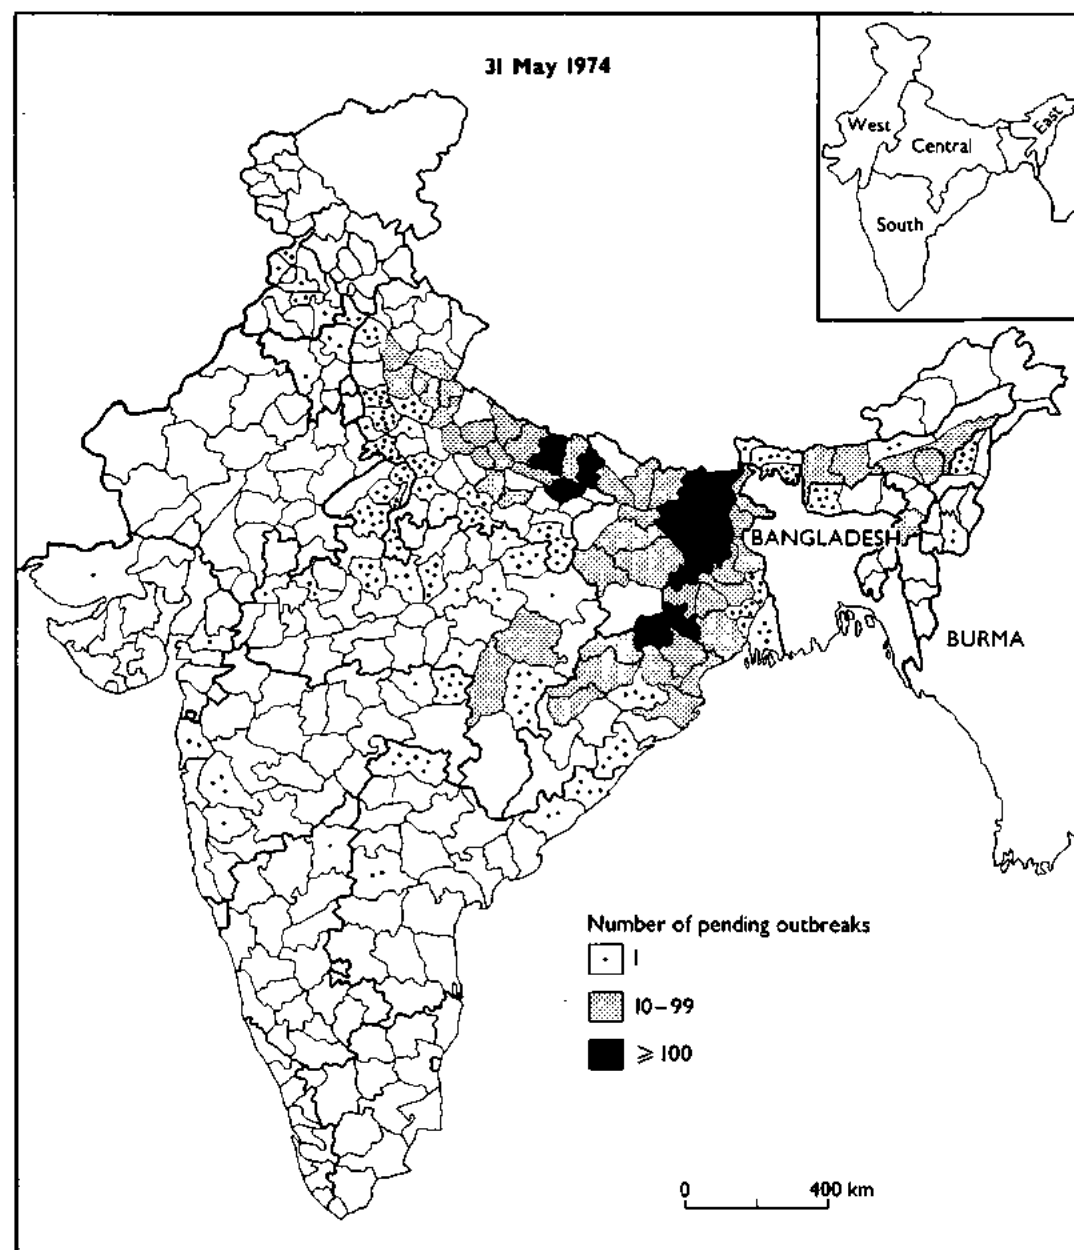

Fig. 15.22. India: number of pending outbreaks of smallpox, by district, as of 31 May 1974.

### The Situation in India as Seen in June 1974

Memorandum, dated 24 June 1974, from the Chief of the WHO Smallpox Eradication unit to all smallpox eradication staff:

"The epidemics of smallpox now occurring in Bihar, eastern Uttar Pradesh and adjacent areas have been the subject of world-wide press interest during the past two weeks with many articles appearing in all major newspapers and news magazines. Providing perspective on the problem has not been easy. While there is no question but that Bihar and eastern Uttar Pradesh are heavily afflicted and represent now the "epicentre" of the global problem, the fact of a far more active programme and more complete reporting unquestionably magnifies the severity of the problem when comparing this year's and last year's data. Whatever the relative magnitude of the problem, it is clear that the most critical battle of the entire programme is now being fought on the Indo-Gangetic plain of Bihar, Uttar Pradesh and the adjacent states. Our success in these efforts over the coming months will be determining in regard to the goal of global eradication.

"The reporting of large numbers of cases as is now the case in Bihar, eastern Uttar Pradesh and adjoining areas, is of real concern but, at the same time, it may also be regarded as an encouraging sign. Unless outbreaks are found, they cannot be controlled. And one must recall the experience in Brazil when, in 1969, surveillance was first introduced into the programme. Smallpox incidence abruptly rose that year to reach the highest level in almost a decade, only to fall to '0' less than a year later. Can we do the same in these other problem areas? Unquestionably we can, provided there is full government support at all levels and that every effort continues to be made to find all cases and outbreaks and to contain them.

"While the epidemics in India have captured the headlines, equally newsworthy are the spectacular achievements in Pakistan. It is apparent that staff at all levels of the programme now realize that eradication is imminent and with this realization has come an even more energetic burst of activity."

approached for help in dealing with smallpox in the 6 southern districts of Bihar comprising Chotanagpur Division. He agreed to assist and the company's Board of Directors approved the expenditure of 7.2 million rupees (US\$900 000) and the assignment of personnel and vehicles. An unusual semi-autonomous public and private sector programme was created in this division, involving personnel and equipment from WHO, Tata Industries, the government of India, the state of Bihar, and OXFAM, a private voluntary organization. The consortium participating in the Chotanagpur Division programme was to function capably and with remarkable cooperation over the following 12 months.

Deficiencies in the containment of outbreaks had proved to be a serious weakness of the programme in most states, particularly Bihar and Assam. Where smallpox outbreaks were few, state surveillance teams had usually assisted local staff in their investigation and in the vaccination of village residents. Where smallpox was widely prevalent, procedures

called for the detection of all cases in the area and the vaccination of those in the 20-30 nearest households. The names of any absent household members were supposed to be recorded and the village visited on a later occasion to ensure that all were vaccinated. This directive was rarely followed, however. In many areas of the world, and indeed in many parts of India, simple containment measures had sufficed to stop transmission. In the more densely populated parts of India, however, they proved ineffective. Many persons left their homes during the day to go to the fields, to market or elsewhere; some who objected to or feared vaccination simply hid themselves and their children when the teams were in the villages; many visited relatives and friends, including those with smallpox, in other villages. The result was that even after intensive containment vaccination, numerous susceptible persons remained and smallpox transmission persisted.

It was therefore decided to systematize the containment activity in a manner that could be readily understood and widely applied and

BY COURTESY OF TATA INDUSTRIES

**Plate 15.15.** One of the 56 surveillance teams in Chotanagpur Division, Bihar State, setting up camp in a tribal village. The programme in Chotanagpur, one of the most seriously affected areas, represented an unusual co-operative effort of groups from the public and private sectors.

that was subject to verification by a supervisor. "Containment books" were designed, printed and distributed in August 1974. One book was used for each outbreak. The name of each person in each of 500 houses surrounding an infected household in a rural area (1000 houses in an urban area) was to be listed in the book and repeat visits made to the village until all persons had been vaccinated and the fact duly registered in the book (Sharma & Grasset, 1975). In a separate section of the book, information regarding each case was recorded.

Three specific standards were also established at this time as indices of the effectiveness of, respectively, surveillance, containment, and outbreak investigation activities. The provision of standards by which a programme in any area could be measured was thought to be helpful in improving the quality of supervision. An indication of the degree of effectiveness of surveillance was the lapse of time between the onset of the first case and the detection of the outbreak. The detection of at least 75% of outbreaks within 14 days of the onset of the first case was felt to be attainable. If adequate containment were performed, all susceptible contacts would be vaccinated and none should develop smallpox once vaccinal immunity had developed say, after 7-12 days. Assuming that it would take several

days to identify and vaccinate susceptible persons, it seemed reasonable to establish a second goal—namely, that no cases should develop more than 17 days after an outbreak was detected. The quality of the investigation of an outbreak was more difficult to measure, but such quantification was considered important because experience had shown that the least well performed part of an investigation was usually the identification of the source of infection. The concept that each individual with smallpox must have been in face-to-face contact with another individual with smallpox just 7-17 days before onset was a surprisingly difficult concept for many to grasp. On investigation forms, many simply listed "sporadic" as the source of infection. To identify the source, however, was vital because often other, as yet undiscovered, outbreaks were unearthed in this manner. Thus, the third goal called for the identification of the source of the outbreak in 90% of outbreaks, a level of success which had been achieved by competent epidemiologists in other areas.

The measurement of progress based on the number of the then existing infected villages and urban *mohallas* (sections of a city) had been initiated in October 1973 in West Bengal and had been introduced in some other states as well, particularly those with a low incidence of smallpox. In June 1974,

### The Problem of Beggars

The containment of outbreaks among beggars proved to be an exceptionally difficult problem requiring imaginative and administratively unorthodox solutions. The isolation of beggars with smallpox in their homes was impossible because most were transients. In fact, isolation either in a house or in a hospital was refused because both the beggars and their families were dependent on begging for their livelihood. Even those actively ill with smallpox travelled from village to village shouting for alms, as was their custom. During 1973, a number of instances were documented in which infected beggars had transmitted smallpox to a dozen or more people and had been the source of many widely dispersed outbreaks.

In 1973 an epidemiologist wrote to propose that beggars with smallpox and their families should be given food and lodging until they recovered. The proposal was rejected by WHO regional office administrators and senior Indian staff, who foresaw this as a precedent to providing support to a legion of beggars. Undeterred, Dr Stephen Jones, a free-spirited American epidemiologist, used his imprest account funds to do just this and submitted a bill of 1800 rupees for the hiring of a house, the purchase of rice, a broom and various other supplies to house a family of beggars. Anticipating trouble in explaining the outlay to WHO's finance officer, Dr Grasset and Dr Foege decided to pay the relatively small bill themselves but argued more aggressively for a change in policy. Eventually, the practice was accepted. During succeeding months, hundreds of beggar families with smallpox were supported in this manner and effective containment of the outbreaks was achieved.

uniform definitions for this method of measurement were developed and it was formally adopted throughout India. Any village or *mohalla* in which a case had occurred within the preceding 4 weeks (subsequently extended to 6 weeks) was considered to be the site of a "pending outbreak". This concept recognized the potential for the spread of smallpox from the patient to susceptible contacts throughout the period concerned and the need to check the outbreak repeatedly to ensure that transmission did not continue. A list was kept in each primary health centre and each district (later, each state) showing the name of the infected village or *mohalla*, the date of onset of each case, the date of discovery, the date on which containment began, the source of infection, and the dates on which supervisory personnel had visited it. The outbreak was not removed from the list until the site was visited and searched again, not less than 4 weeks (later, 6 weeks) after the onset of the last case.

As at the end of June 1974, there were 6401 pending outbreaks in 17 states and Delhi Municipal Corporation (Table 15.25).

With additional resources and an increased complement of supervisory personnel, state-wide search and containment programmes continued throughout the summer. Most of the resources were assigned to Assam, Bihar,

Uttar Pradesh and West Bengal, in which searches were conducted monthly. In Bihar alone, 35 national and international epidemiologists and more than 100 state epidemiologists and paramedical personnel assisted state, district and local health personnel (Jha & Achari, 1975); in Uttar Pradesh, there were 27 national and international epidemiologists and 19 state surveillance teams (Srivastava & Agarwala, 1975). Most other states conducted one search during this period, although some conducted two. The number of pending outbreaks began to decline sharply, and with fewer outbreaks surveillance teams were able to provide increasingly better supervision of search and containment activities. The quality of both procedures rapidly improved. In addition, the teams devoted more time to visiting markets and schools to inquire about rumours of possible cases. The number of pending outbreaks decreased to 4606 at the end of July and to 3267 at the end of August. The first hopeful note since February was sounded on 26 August in a WHO South-East Asia Smallpox Regional Surveillance Report: "The opportunities for interrupting smallpox transmission in India, Nepal and Bangladesh are better than at any time since the programme started."

By the end of September, there were only 2124 pending outbreaks, of which 1727

<sup>a</sup> No outbreaks were recorded in the union territories of Andaman and Nicobar Islands, Arunachal Pradesh, Chandigarh, Dadra and Nagar Haveli, Goa, Daman and Diu, Lakshadweep, Mizoram and Pondicherry.

(81%) were in Bihar (Table 15.25; Fig. 15.23). The north-eastern districts of Purnea and Katihar in Bihar had more than 600 pending outbreaks, but in only 8 other districts were there more than 50. Almost none were to be found in all of southern and western India. In September, 4674 cases were reported, one-tenth the number recorded in May.

The staff were optimistic but still concerned. The analysis of data from previous years indicated that some increase in transmission occurred at the beginning of October, coinciding with an increase in the numbers of persons travelling from place to place to attend festivals and marriages. Thus, there was a heightened concern about the spread of smallpox over greater distances. Moreover, active outbreaks persisted in 50 municipalities which were recognized to be important sites of dissemination to rural areas. Finally, in Assam, the number of pending outbreaks had actually increased from a low of 50 in August to 64 in September; in this state, field operations were greatly hampered by floods, a poor trans-

portation network and a less than adequate health service. Its neighbour, Bangladesh, appeared to pose no threat, since there were only 163 infected villages in the country at the end of September, a competent programme was in place and the numbers of reported cases and outbreaks were declining as rapidly as in India. In Nepal, to the north, only 4 outbreaks were detected in September 1974.

Additional measures were implemented in October to strengthen surveillance and containment. In all urban areas with active outbreaks, a house-to-house search was conducted every 2 weeks. Additional personnel were assigned to work in Assam. Perhaps of greatest importance was the decision to offer throughout India a reward for the notification of a previously unreported outbreak of smallpox in which a case had occurred within the preceding 6 weeks. This, it was hoped, would permit earlier detection of cases and discourage the suppression of reports which, despite all efforts, remained a problem in some areas. In addition, smallpox cases were sometimes hidden by villagers who held

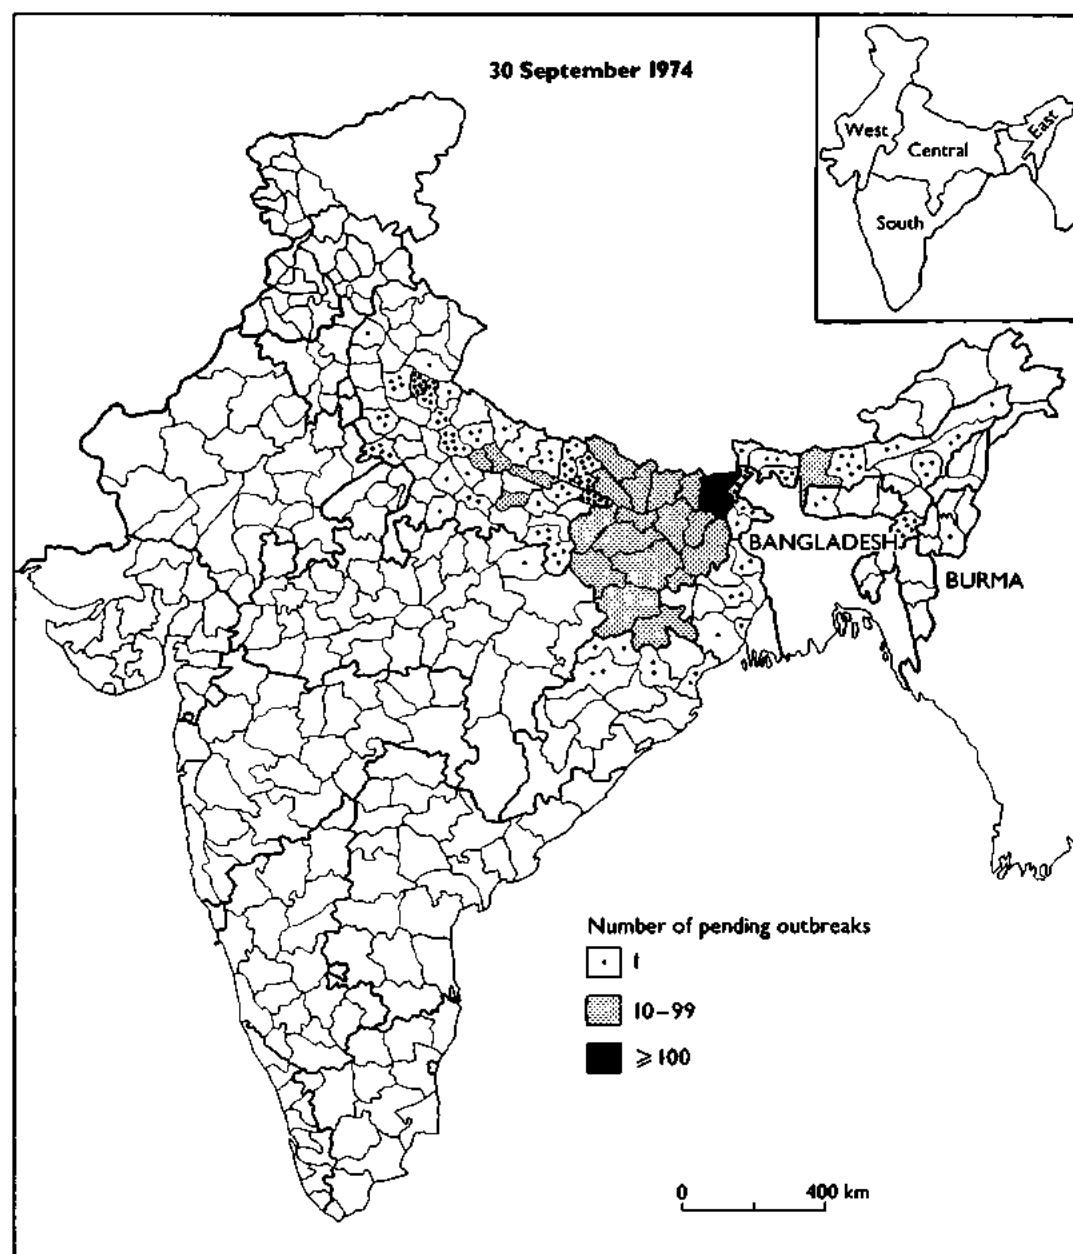

Fig. 15.23. India: number of pending outbreaks of smallpox, by district, as of 30 September 1974.

religious objections to vaccination or feared that patients might be removed to hospital. The offer of a reward had originally been proposed in 1972 in areas with a low incidence of smallpox, but many health officials had been reluctant to adopt the practice, fearing that it would create a precedent with regard to the reporting of cases of other diseases. However, as has previously been described, 5 of the southern

states began offering rewards of 10-25 rupees, following the extensive suppression of reports which resulted in the Gulbarga (Mysore) outbreak in 1972. Early in 1974, some other states that had a low incidence or were thought to be smallpox-free also began to offer a reward, which was now increased to 50 rupees. The inducement had not been particularly effective, however, because information about the reward was not widely

### Market Searches

Surveys in the traditional weekly markets, held throughout India, were especially useful in detecting cases of smallpox. It was found that 2 searchers could readily question 300–500 market visitors in the course of a working day (Basu & Khodakevich, 1978b) and obtain information about cases in villages 10–20 kilometres distant. It was a technique widely employed by surveillance teams.

Posters showing a smallpox patient and announcing the reward for reporting a case were posted at the entrance to the market and in tea-shops. At each entry point 2 workers were stationed, one of whom asked those entering the market if they knew of cases and which village they were from; the second worker recorded the information. Later, the searchers moved to the tea-shops to continue the questioning. The investigation of all reported or rumoured outbreaks was undertaken the following day.

To assess how effective the market search technique had been, a special study was conducted in a mountainous area of Assam (Khodakevich & Rao, 1978) in January 1976. In a district comprising 695 villages scattered over an area of roughly 15 by 55 kilometres, 7 markets were searched to determine whether outbreaks occurring over the preceding 3 years could be detected. The searchers were health workers who had not been associated with the programme and had no information about previous smallpox in the area. Visitors to the market reported 64 villages as having been infected with smallpox during the preceding 3 years. Investigation revealed that 18 of the villages were in another district, 2 had outbreaks in 1970, 2 had outbreaks of chickenpox, and in 8 others no evidence of outbreaks could be found. The remaining 34 villages in which smallpox was reported to have occurred included all 13 villages which had had outbreaks in 1975, 17 out of 32 of those with outbreaks in 1974 and 4 out of 13 of those with outbreaks in 1973. Although the market searches did not detect all outbreaks, they served to provide a great deal of information at a minimum cost in manpower.

disseminated by the health workers, who wanted to claim the money for themselves. To overcome this problem, it was decided to offer 50 rupees to the person first reporting a previously undiscovered outbreak and 50 rupees to the health worker who received the report.

Containment measures were also strengthened as some surveillance-containment teams, which now had fewer outbreaks to contend with, began to stay in infected villages overnight to ensure that all residents were vaccinated. One or two local inhabitants, termed "watchguards", were hired to stay at each infected house to prevent the patient from leaving and to vaccinate anyone who could not be dissuaded from visiting. Eventually, 4 watchguards were engaged to guard each house with a patient, 2 of them working during the day and 2 at night. This meant that if one watchguard had to absent himself, one would remain on duty. When it was found, in some areas, that visitors avoided the watchguard by entering through a back door, the back entrance was barricaded. Observing that new outbreaks were often

found in villages adjacent to those infected, the teams began an increasingly intensive search in a 5-mile (8-kilometre) radius around each infected village.

Information on the means by which outbreaks were actually detected are available for 3798 outbreaks from mid 1973 to mid 1975. The data for the latter half of 1974 and for the first half of 1975 show that an increasing proportion of the outbreaks was being notified by the public and a lesser proportion was detected by periodic search (Table 15.26). In the non-endemic states, notification by the public played a more important role, the proportion of outbreaks so notified increasing from 15% in the first 6 months of 1974 to 29% in the second 6 months and to 36% in 1975.

The outbreaks were detected increasingly earlier after the onset of the first case (Table 15.27), although the standard which called for 75% to be detected within 14 days was never reached. The outbreaks persisted for a shorter time (Table 15.28) but in some of them cases continued to be found more than a month after detection. With earlier detection

and better containment, the outbreaks, as might be expected, were less extensive (Table 15.29).

Assessment of the ever-more-thorough searches was modified to determine the proportion of villagers who were aware of the reward for reporting cases. It was assumed that if the existence of the reward were generally known, cases would not be hidden for long. Personnel searching for cases were instructed to convey the fact of its existence to all the villagers. Radio, posters, leaflets, rickshaws with loudspeakers and announcements at weekly local markets were also used as a means of information.

During the autumn, the number of pending outbreaks fell steadily, from 2124 at the end of September to 980 at the end of October and to 343 at the end of November (Fig. 15.24), but then the rate of decline slowed considerably. Almost as many new outbreaks were being added to the list as were

being removed. The winter season of more rapid transmission had begun. The numbers of outbreaks and cases were at a record low, but, if smallpox transmission was to be interrupted, even more rigorous methods of case detection and containment would be required.

Concern about the programme's progress suddenly turned to alarm in mid-December

### Status of the Programme in Early December 1974

Memorandum, dated 9 December 1974, from the Chief of the WHO Smallpox Eradication unit to all smallpox eradication staff:

"The autumn saga of 1974 has been marked by weeks of unexpectedly rapid decreases in the number of pending outbreaks in Asia interspersed with weeks when there has been little or no decline. At present, we seem to be again in the latter phase. Does this signal the beginning of a phase where seasonally increased rates of transmission overbalance our capability to contain the outbreaks *or* does it represent but a pause in the countdown as we regroup to redeploy forces and to tighten up containment procedures and so recommence the countdown? Unquestionably, a greater effort is required during the winter months to ensure containment of each outbreak, but the task can be accomplished.

"With search activities now reasonably well developed in most districts and with market searches and the system of rewards serving to assure discovery of outbreaks missed in search, it seems to me that now is the time to deal far more rigorously with containment measures. In many areas... staff have not dealt with containment as rigorously as is now required. This is not surprising. During the summer and early autumn months, further spread of smallpox occurred only infrequently even when containment measures were less than optimal. Inevitably, emphasis shifted to improving the search procedures, sometimes perhaps at the expense of the arduous and meticulous work required to assure 100% containment. With increased rates of transmission and more population movement, containment procedures which were effective in October are no longer so.

"At this stage, and with the comparatively few outbreaks we have, *every patient* must be subjected to 24-hour guard and, as required, food provided to the families to provide further incentive for them to stay put. If the guard is fully effective, every subsequent contact will be protected by vaccination. But *frequent* supervision by epidemiologists and senior staff is mandatory if the system is to work. Then begins the now necessary but arduous task of tracing all contacts of the patient from the time of onset of rash. This procedure is in effect in some areas but, as of the time of my visit two weeks ago, it was not in effect everywhere.

"Most important now is for each epidemiologist to consider each new outbreak as being indicative of a possible failure in the system. The question for each outbreak must be asked—'Why did this outbreak occur and what should be done to prevent a repetition of the episode?'"

1974 as major epidemics unexpectedly began in Bangladesh. Catastrophic floods, the worst in 20 years, had swept the northern districts of Bangladesh in August and September and, with the subsequent famine, tens of thousands of refugees migrated to other parts of the country. In December, smallpox began spreading rapidly and once again infected the major cities. The most heavily affected areas were along the northern Bangladeshi-Indian frontier and because of frequent travel across the border, numerous importations were to be anticipated. Of particular concern were the eastern states of India, in which the health services and the smallpox eradication programme itself were the least able to cope.

Realization that a difficult spring might lie ahead was soon followed by the ominous discovery of a cluster of outbreaks at a major

pilgrimage site of the Jain religion about 85 kilometres from Patna, the capital of Bihar (Jha & Achari, 1975). The largest outbreak was detected in December 1974 at Puri village, in which the founder of the Jains had died 2500 years earlier. Forty households were infected at the height of the pilgrimage season. Complicating the problem was resistance to vaccination, common among Jains. A special appeal was made to the principal religious leader, who agreed, reluctantly, to recommend vaccination. The entire village was quarantined by the Bihar military police. Twenty-four-hour watchguards were posted at the houses of infected persons and at key areas in the village. A community kitchen was set up to feed patients so they would not have to leave their homes for food. Pilgrims were not allowed to enter sacred pilgrimage

Fig. 15.24. Bihar State, Uttar Pradesh State, West Bengal State and the rest of India: number of pending outbreaks of smallpox at the end of each month, by month, 1974.

areas until they had been vaccinated. Although smallpox spread to 5 adjacent villages, the outbreak in Puri was finally controlled by the end of February 1975.

Elsewhere in the district, the number of outbreaks had increased from 16 to 75. Assessment revealed poorly conducted search operations and inadequate containment. Emergency measures were introduced. Whenever an outbreak was discovered, 20–25 vaccinators were dispatched to the infected village; containment vaccination was completed within 48 hours; 24-hour watchguards were posted at every infected household; and food was brought in to ensure household quarantine. Entire villages were cordoned off when necessary. Instead of a few vaccinators, dozens were assigned to each newly discovered infected village and camped there until no active case remained. In all, 102 new outbreaks were discovered in Bihar in January 1975.

#### "Operation—Smallpox Zero", January 1975

With smallpox present in only 285 of the more than 575 000 villages of India at the end

#### Problems in Containment: a Report by a Supervisor in Bihar, May 1975

"We have the misfortune to have to inform you of a new case of smallpox in the Painathi outbreak, a 4-month-old unvaccinated male with onset of rash on 30 April. The household is only 10 metres from a household where a severe case occurred on 13 April.

"The patient and his mother left Painathi on 29 March, 2 days before containment began. The mother was enumerated but the existence of a child was not made known. They returned on 14 April but their presence was concealed by the father. Searchers went daily to each house in the village to vaccinate and to inquire about fever and rash. Dr Khan and Dr Briedert personally visited this house to find out if all the vaccinations were successful and if this woman had returned. The father of the child, however, lied to them.

"The family had been resistant and uncooperative from the start. After enumeration, vaccination was possible only when we climbed over the compound walls and forcibly inoculated each family member. After a rumour reached Dr Khan, who had been staying in the village, he had to use a trick to gain entrance to the house. He asked for a glass of water and this was denied. He knew by custom that they had a case of smallpox inside the house because nothing can be given when a case of smallpox is in the house of a member of this religious sect.

"Dr Briedert is now staying *inside* the infected house. A room-by-room search has been done and will continue daily. All visitors have been traced—all had been previously vaccinated. The mother was vaccinated on 2 May. She has a primary scar and we can only hope that she will not develop into a case. We are nonetheless isolating her and keeping her under close observation for the next 14 days."

**Plate 15.16.** The search for smallpox cases intensified throughout 1975 as efforts were made to detect all cases of fever accompanied by rash. **A:** A village headman brings a child to smallpox eradication staff for confirmation of diagnosis. **B:** A search worker shows the WHO smallpox recognition card to children. **C:** Posters and writing on a wall advertise a reward of 100 rupees to anyone who detects a case of smallpox.

of December 1974 and with reasonable confidence that there were few undetected outbreaks, it appeared that the elimination of smallpox was at hand. However, from the experience of the past year in Bihar, it was clear that smallpox could spread rapidly in this densely populated area during the winter and early spring. Analysis of the experience in the autumn of 1974 showed that deficiencies in containment were primarily responsible for the failure to stop outbreaks. Vaccination of the population of affected villages was not as rapid as it might have been, visitors to the villages were often not vaccinated and some villages were declared free of smallpox without a thorough follow-up search. Although searches were conducted within a 5-mile (8-kilometre) radius of infected villages, some outbreaks traced to those villages were found to occur at distances of up to 16 kilometres.

At the end of December, new instructions were issued by the government entitled "Operation—Smallpox Zero". The following passages are extracts from the instructions:

"With the outbreaks so few in number, each outbreak must now be dealt with as an *absolute* emergency with maximum mobilization of staff and volunteers. As much concern should be directed to each outbreak as would be directed to control an outbreak in a non-endemic country such as in Europe. *Never* should a case occur more than 21 days after discovery of an outbreak.

"With the very small number of outbreaks present and with fully effective containment, smallpox transmission should be stopped in India in not more than 6–8 weeks. An all-India, all-out effort to achieve this objective will commence immediately and at all levels of the programme. These activities will be conducted under the code name 'Operation—Smallpox Zero' with the objective that no case of smallpox would occur after February.

#### "PROCEDURES

"1.0 A special Central command comprised of senior experienced Government and WHO staff will visit every new outbreak detected after 1 January and will revisit every outbreak in which a case is discovered more than 21 days after its discovery to ensure that every possible measure is being taken. These will supplement, not replace, other supervisory visits. To facilitate this, all new confirmed outbreaks must be reported immediately by cable to the State Programme Officer and to New Delhi. Any case occurring more than 21 days after discovery of an outbreak must similarly be reported by cable.

"2.0 Every outbreak must now be dealt with rapidly and with a massive containment effort.

Instead of three or four workers, the containment teams should consist of 15 to 20 workers or more, headed by the District Medical Officer of Health assisted by a national or WHO epidemiologist. In urban areas, this number may be several times greater. *Vaccination in an infected village/mohalla must be essentially completed within two or at most three days.* Three or four workers must camp in the village/mohalla until all scabs have separated from the last case. Two watchguard-vaccinators must be assigned to each infected house to maintain a 12-hour watch during the day while a second pair maintains a 12-hour watch at night. Watchguards will be responsible for (1) vaccinating all persons visiting the houses of smallpox patients; (2) identifying all household contacts who leave to go to other areas; (3) maintaining isolation of smallpox cases; and (4) maintaining an hour-by-hour log book record of activities and of movement of people in and out of the households. Food, necessary medicines and housing may be supplied to the family of an infected patient on a daily basis to ensure cooperation and isolation. Smallpox containment field books with complete enumeration of the village/mohalla must be completed on each outbreak.

A typical containment team might include:

1. 4 watchguard-vaccinators for each infected house
2. 8 vaccinators of which 4 should camp each night in the village
3. 2 motivation workers (village-level workers who know the village/mohalla and are respected by the villagers)
4. 1 supervisor and 2 vaccinators to trace household contacts who have gone to other areas
5. 3 supervisors
6. 1 containment team leader.

"3.0 House-to-house search will be made in a 10-mile [16-kilometre] radius around an outbreak as well as in high-risk areas which may be outside the 10-mile radius. In the urban areas the surrounding mohallas will be searched in a similar manner. This will be followed in two weeks by a second house-to-house search within a five-mile [8-kilometre] radius to find cases which might have been in the incubation period during the first search.

"4.0 In case of a death, the vaccinator will accompany the remains to be certain that the body is properly disposed of and that all garments are buried. All attending the funeral will be vaccinated, a register of participants and their addresses will be prepared and all villages from which they came placed under surveillance.

"5.0 After 1 January, a laboratory specimen from one or two cases in each new outbreak will be collected."

It was decided that the periodic routine search programmes would consist of house-

to-house visits, whereas previously searchers had checked only a sample of houses in each village. The reward for reporting a case was increased from 50 rupees to 100 rupees. Each suspected case—i.e., one with a rash and fever—was to be recorded in a "rumour register", which was established at every primary health centre. Each patient was to be visited immediately by the local health officer and the diagnosis confirmed by an epidemiologist. If the diagnosis was uncertain, it was to be considered smallpox and watchguards were to be posted. By experience, it was found that good performance on the part of watchguards could be ensured by the simple expedient of not paying them until they were relieved of duty. If, at any time, a watchguard was not found on duty, all 4 were dismissed without pay and new watchguards were recruited. Containment vaccination was to include all persons within a 1-mile (1.6-kilometre) radius of the outbreak. In all, this meant vaccinating some 4000–5000 people in rural areas and 80 000 in urban areas (Sharma & Grasset, 1975). Search throughout an area with a 10-mile (16-

kilometre) radius, performed by locally recruited and trained staff, usually encompassed 300–600 villages. The costs of a typical containment operation in 1975 were estimated by Ježek to be about US\$2700 (Table 15.30).

Investigations into the source of the outbreak were intensively pursued by national and international epidemiologists, but now, instead of notifying neighbouring states or districts of the existence of a suspected source, they themselves proceeded to the locality. This ensured that the sources would not be missed because of difficulties with telegraphic communication or confusion due to information being received from illiterate villagers and the consequent need to spell village names phonetically.

To guard against importations from Bangladesh, special surveillance teams were assigned and special searches conducted in Muslim Bengali areas and communities in India. Special attention was given to Calcutta, in which repeated night searches were made among the 48 000 street dwellers (Spring, 1975).

Table 15.30. India: estimated manpower employed and costs of a typical containment operation, 1975

	Rupees (Rs.)
<b>1. Substantive staff</b>	
Epidemiologist, 21 days at Rs. 100 per day	2 100
Junior medical officer, 42 days at Rs. 35–50 per day	1 764
Paramedical assistant, 42 days at Rs. 15–30 per day	924
Driver, 102 days at Rs. 10–15 per day	1 224
<b>Total:</b>	<b>6 012</b>
<b>2. Additional (temporary) staff</b>	
Watchguards (assume 2 infected houses): 8 workers, 42 days at Rs. 5 per day	1 680
Search workers to search 10-mile radius (assume 500 villages), 300 search-days at Rs. 5 per day <sup>a</sup>	1 500
Search workers to do repeat search of 10-mile radius	1 500
Vaccinators to vaccinate the village population (assume 1000 population): 20 vaccinators, 5 days at Rs. 5 per day	500
Vaccinators to vaccinate population in a 1-mile radius: 20 vaccinators, 15 days at Rs. 5 per day	1 500
Supervision (at 1 supervisor to 5 worker-days)	
(a) for search of 10-mile radius, 60 supervisor-days at Rs. 10 per day	600
(b) for repeat search	600
(c) for watchguards, 1 supervisor, 42 days at Rs. 100 per day	420
(d) for vaccinators of village, 4 supervisors, 5 days at Rs. 40 per day	200
(e) for vaccination of population in a 1-mile radius, 4 supervisors, 15 days at Rs. 40 per day	600

Fig. 15.25. Importations of smallpox from Bangladesh to India, 1975.

"Operation—Smallpox Zero", begun in January 1975, proved to be most successful. From November to December 1974, the number of pending outbreaks had decreased from 343 to 285 (17%); in January, to 194 (32%); and in February, to 113 (42%). As had been feared, cases were imported from Bangladesh, 30 importations being detected in West Bengal, Assam and Tripura (Fig. 15.25). Two-thirds were detected within 2 weeks of the onset of illness in the first case and only 8 additional outbreaks occurred as a result of further spread.

In all, only 308 outbreaks and 1436 cases were detected in India after 1 January 1975 (Tables 15.31 and 15.32). All were in the eastern part of India except for 10 in the far western Kutch desert of Gujarat, introduced by migrants probably infected in Bihar.

In April, 115 000 health workers undertook a week-long, house-to-house search throughout the whole of India. Independent assessment of some 5% of villages showed that 85%–96% of all villages in the various states had been searched. Among 574 517 persons interviewed, 61% knew about the reward for reporting a case and knew the amount of the reward. Only a few

outbreaks were found, all of which had resulted from importations. Smallpox had been virtually eliminated during the season of most rapid transmission. In May, the last cases and outbreaks in India were discovered.

### **The Last Case in India, May 1975**

As in many other countries, so in India the last case presented some unusual features (Ježek et al., 1978a). Saiban Bibi, a 30-year-old homeless Bangladeshi beggar, developed a rash while living on the Karimganj railway station platform in Assam, where she was begging for food. She had contracted smallpox from a patient in Sylhet District, Bangladesh. On 26 May, she went to the Civil Hospital in Karimganj, which forthwith notified the District Health Officer. Accompanied by a WHO epidemiologist and the state surveillance team, he immediately went to investigate.

The situation was alarming. For the first 4 days of illness, the patient had lived on the platform of the railway station, the gateway to the states of Assam and Tripura and the union territory of Mizoram. Between 22 and 26 May, 9 trains had stopped at the station and 4535 railway tickets had been issued to 68 different towns and cities. A programme was immediately launched to search and vaccinate in the city wards in which the railway station and the Civil Hospital were situated. Later, containment activities extended to the whole town, as well as to all villages visited by the patient since 21 May. Railway authorities were instructed to intensify surveillance activities in and around the railway stations and railway colonies. All district health authorities in Assam and neighbouring states through which the railway passed were asked to initiate intensive searches during the subsequent 14 days. Special searches were conducted in all villages within 10 miles (16 kilometres) of the district border with Bangladesh.

The patient was isolated and 4 watchguards were stationed in the isolation ward for round-the-clock duty. All patients, visitors and hospital staff, together with their relatives, were enumerated and vaccinated. The hospital was closed to visitors and the discharge of patients was stopped. One watchguard was placed at the railway station to carry out surveillance and vaccination.

Three border checkpoints were established and all incoming and outgoing travellers

were checked and vaccinated. All border security forces and police outposts were alerted to look for possible cases.

Surprisingly, despite the time of year and the many persons who had been in contact with the patient, no further cases were found.

### **India Celebrates Independence Day and Freedom from Smallpox, August 1975**

Six weeks passed after the onset of illness in the last patient and the last outbreak was deleted from the list of pending outbreaks. On 1 July, the reward for reporting a case was increased to 1000 rupees (US\$125), the equivalent of 4 months' salary for an Indian labourer. This was done with some trepidation, since it was feared that unscrupulous persons might smuggle smallpox cases from Bangladesh to claim the reward. Indeed, on one occasion this did happen, but the ruse was readily detected. With a reward of this magnitude, thousands of patients with rash and fever were reported to the health authorities. Each was investigated; none proved to have smallpox.

On 15 August 1975—India's Independence Day—the government held a special celebration honouring India's freedom from smallpox, which was attended by the Director-General of WHO.

Less than 3 months had elapsed since the onset of the last case, and with smallpox still present in Bangladesh the staff were understandably apprehensive that at the last moment another focus might be found. The search continued, but an unexpected event of quite another type occurred. On the night of 15 August, the President of Bangladesh was assassinated. The government closed the airports and sealed the borders—to the extent that this was possible. It was feared that there might be yet another mass exodus of refugees.

An emergency surveillance programme was immediately put into operation, focusing on Bengali-speaking areas. Possible migration routes were identified, dozens of surveillance posts were set up at border crossings, special searches were conducted in designated high-risk areas and surveillance was intensified in Calcutta. Happily, the refugees were few and no further importations occurred.

On 16 October 1975, the last case of smallpox occurred in Bangladesh and the 2-year search began to confirm eradication throughout Asia.

### Why the Smallpox Eradication Programme Succeeded

Two papers have been published by members of the smallpox eradication staff which comment on distinctive features of the smallpox eradication programme in India that were crucial to its success. Extracts are given below:

"The strategy used and the manpower and other resources provided ... greatly contributed to the rapid success of the programme; but without the passion given to the planning and implementation of the programme by the workers, achievement would not have been possible. Jawahar Lal Nehru once said 'Planning would be meaningless unless behind the plan there was a passion—passion with a tinge of anger at delays, anger at anybody not doing his part, anger at not achieving where achievement is possible'. The national and WHO staff have fought with passion the battle against smallpox ... Hundreds of men and women—nationals and internationals—have worked up to 18 hours a day for seven days a week in the belief of an ideal which they have put above their personal happiness, their family life, their career and their health. The central level staff both of the WHO and the Government of India have spent on an average three weeks a month working in the field throughout the country to train, motivate, encourage the local staff. During the 1974 summer epidemic of smallpox in Bihar and [Uttar Pradesh], a number of WHO, central and state officers were publicly laughed at for having predicted that their states and the country would be free of smallpox in less than a year ... Men and women from different states in India and from many countries of the world put aside their racial, national, religious or social prejudices and bore together all the difficulties and hazards. Many took risks in putting aside conservative regulations, red tape and antiquated technical methodologies, when these threatened to delay their task or obstruct the path to success. The toughest of men and women on many occasions were on the verge of discouragement—from physical tiredness and mental frustration, when having to cope with hundreds of infected villages in their area of responsibility. They persevered, waiting days, weeks, sometimes months, until it was possible to send them more men, better vehicles, funds for petrol, etc. In the smallpox offices in New Delhi and also in the state, district and block headquarters, medical officers, administrators and secretarial staff worked most of the days far into the night, over the weekends and public holidays so as to make sure that those in the field received the necessary support. However, even during the most difficult stages of the programme, men and women in the field and offices discovered like Rabindra Nath Tagore that they 'acted and behold duty was joy'." (Sharma & Grasset, 1975.)

"The decentralisation of authority to implement the strategy to the district health authorities and epidemiologists who were responsible for proper utilisation of available resources resulted in the early detection and effective containment of large numbers of disease foci in the shortest possible time and the consequent quick interruption of transmission. If one considers that ... India ... [was] spending over 40 million rupees a year for the past ten years on NSEP and [that an] additional amount of about Rs. 20 million each [year was being spent by WHO] during the campaign years 1973–74 and 1974–75 ... it becomes apparent that it has not been the quantum of money spent but the manner of doing it which made all the difference between success and failure. Relative freedom at district levels to take on-the-spot decisions to spend this additional amount ... greatly contributed to the realisation of smallpox free status. Administrative and operational restraints in implementing the strategy were also minimal.

"All the national health programmes have built-in evaluation methods. The interval between occurrence of a defect/problem and its detection and the interval between the detection and correction has always been considerable ... In this smallpox campaign the continuous monitoring of the smallpox status, feedback from the field staff and the authority for taking on-the-spot decisions regarding fiscal, administrative and technical matters have narrowed down the unknown and the unsolved problems to the minimum." (Dutta et al., 1975.)

### Morbidity and Mortality Data

Information regarding the age, sex, vaccination status and survival or death of the patient was obtained for all cases in India. However, data were tabulated nationally for only a proportion of the total for the years 1974–1975 (Basu et al., 1979). These data were obtained from 4 high-incidence states and 13 low-incidence states and union territories, although most of the cases were from the former group. The age distribution of cases and case-fatality rates were similar to those observed elsewhere in the Asian sub-continent (Table 15.33).

Data are available for 23 546 of the 189 439 cases which occurred in 1974–1975. In all, 31% occurred in individuals less than 5 years of age, 40% in those aged 5–14 years, and 29% in those aged 15 years and over. The disease was equally prevalent among males and females.

A similar distribution of cases by age and sex was observed in all states with a high

incidence. Imported cases in smallpox-free states, however, occurred predominantly in males (64.6%) in the older age groups, 18.7% being in men aged 50 years and over. This was attributed to the occurrence of many cases among migrant labourers and pilgrims, a much larger proportion of whom were adult males.

Data regarding the vaccination status of 14 463 cases from the same 17 states and union territories reveal that two-thirds of the persons concerned were unvaccinated (Table 15.34). Patients were classified as “unvaccinated” if they had no vaccination scar (regardless of whether they claimed to have been vaccinated) or if they had been vaccinated during the incubation period of the disease, too late to prevent infection.

The proportion of cases among individuals with an apparent vaccination scar was markedly higher than in other countries. This is explained by the frequent occurrence of vaccination-like scars associated with the use of rotary lancets in which secondary bacterial

Total	4 767	32.9	9 696	67.0	14 463

infections occurred but vaccinia virus did not grow. Most of the cases among "vaccinated" children under 5 years of age occurred in Bihar and Madhya Pradesh, in which, as late as 1973, rotary lancets were still being used in some areas, especially the large municipalities. In Andhra Pradesh, in which the use of rotary lancets was abandoned in 1969, only 15.4% of cases occurred among those with what appeared to be a vaccination scar.

Case-fatality rates in India varied from 21% to 31% during 1950-1967 but for most years they were in the range of 25-30%. During the course of the eradication programme, the case-fatality rate dropped steadily, from 31.2% in 1967 to 16.6% in 1974 and to 12.3% in 1975 (Fig. 15.26). The decline is accounted for by an increasing completeness of the notification of cases.

Initially, most cases and deaths were reported from infectious disease hospitals, to which the more seriously ill were taken and which recorded high case-fatality rates. As time progressed, differences between case-fatality rates in the various states narrowed considerably. Moreover, a much higher proportion of cases in otherwise smallpox-free areas was found among older children and adults, who experienced a lower case-fatality rate than did young children. Data for 23 546 cases that occurred in 1974-1975 show an overall case-fatality rate of 17.4%, but among infants under 1 year of age the rate was 43.5% whereas it was only 6.5% among the 15-19-year-olds. Although wide variations in case-fatality rates were observed in different epidemics, these variations were considered to be due to differences in the age distribution of the cases, the nutritional status of patients, and the history of previous vaccination.

Fig. 15.26. Case-fatality rates for India and the states of Andhra Pradesh, Assam, Bihar, Gujarat, Haryana, Jammu and Kashmir, Karnataka, Madhya Pradesh, Maharashtra, Orissa, Punjab, Rajasthan, Tamil Nadu, Tripura, Uttar Pradesh and West Bengal, by year, 1967-1975. Each dot represents the case-fatality rate in a state in a year. For each year rates are plotted only for the states that recorded at least 100 cases that year. The bold lines denote the overall rate for India in the year shown.

## NEPAL

### Introduction

Epidemiologically, Nepal was a mountainous extension of the Indian states of Bihar and central and eastern Uttar Pradesh, but its programme differed significantly from that in India. Of the country's 10.8 million population (in 1967), 37% lived in the Terai, a northern strip of the broad Ganges river plain (see Fig. 15.1), which in Nepal was about 25–35 kilometres wide; another 53% lived in the adjacent Middle Hills area, which ranged from 30 to 50 kilometres in width. Most of Nepal's population thus lived within some 80 kilometres of the border with India and the majority were Hindu. Many had relatives in adjacent areas of India, and travellers and migrant labourers moved freely across the border. Roads were few, communications were difficult and the health services and other governmental structures were in an early phase of development.

In 1962, a WHO nurse working in Nepal assisted in the development of a pilot mass vaccination campaign in the Kathmandu valley, comprising 3 of Nepal's 75 districts with a population of 500 000. In 1968, the campaign was extended to other districts and by 1973 it included the entire country. Little was done to develop a reporting system until 1971. Data prior to this time represent only a partial enumeration of cases in the Kathmandu valley.

Strategically, the programme in Nepal was initially not of high priority in the global strategy because eradication there depended on the progress of the campaign in India, particularly in Bihar and Uttar Pradesh. Moreover, the mainly mountainous terrain, the predominantly rural population and the poor communications between villages in Nepal suggested that smallpox transmission could not be long sustained in most of the country. Since the population of the Terai was only about 4 million—the equivalent of 2 districts of India—it was expected that the interruption of transmission in that area and in the country as a whole would not constitute a major problem once smallpox had been controlled in India.

Because the health structure in Nepal was rudimentary and vaccine was available to only a small proportion of the population, additional WHO support was provided from 1968. The eradication programme was in-

tended to make vaccination more widely available initially in the most populous areas along the border with India. Three years later, a plan was implemented to extend reporting and surveillance–containment measures progressively throughout the 75 districts. Progress in achieving these goals was remarkably rapid: by 1972 each outbreak was being investigated and contained and its source identified. Continuing transmission was, in fact, largely stopped in that year. Epidemic smallpox in the neighbouring Indian states of Bihar and Uttar Pradesh, however, resulted in an additional 239 outbreaks in 1972 and 1921 cases during the period 1973–1975. Most of these outbreaks could be traced directly or indirectly to importations and although they sometimes remained undetected for many weeks and were not always well contained, smallpox did not usually spread widely. On 6 April 1975, the last known case of smallpox occurred in Nepal as a consequence of an outbreak resulting from an importation from Bihar.

### The Country: Geographical and Socio-cultural Considerations

Until 1951 Nepal, ruled by hereditary prime ministers, had been closed to the outside world, and no organized health services or educational facilities existed. When a constitutional monarchy was instituted in 1951, Nepal began the arduous task of building a transport, communication, health and educational infrastructure. Because of the mountainous nature of the country and the dearth of human and natural resources, progress was slow. Throughout the 1970s, Nepal remained one of the world's least developed countries.

Administratively, the country was divided into 14 zones, which were subdivided into 75 districts; the population of a district ranged from 7000 to 350 000, a far smaller figure than that for a district in India. The smallest administrative unit was the panchayat, of which there were some 4000.

Until the 1960s smallpox had occurred widely throughout Nepal. According to a health survey conducted in 1965–1966, 24% of people over 30 years of age in the capital city of Kathmandu bore the facial pockmarks of smallpox, as did 13% of those aged 10–29 years and 6% of children under 10 (WHO/SE/78.107, Shrestha). Variolation

was known to have been widely practised until recent years and many older persons bore the resulting scars. However, unlike the situation in Afghanistan (see Chapter 14), the practice had died out in Nepal by the time the Intensified Smallpox Eradication Programme began. No cases attributable to variolation were discovered during the course of the programme.

As in India, smallpox epidemics were reported to have occurred approximately every 5 years, the last having happened in 1958 (WHO/SE/78.107, Shrestha). However, up to 1963, there was no reporting system; indeed, until 1971 few reports were received from anywhere except the small districts comprising the Kathmandu valley, the site of the capital city. Some Nepalese, especially those living in the Terai, had been vaccinated in India, as had some living near Kathmandu or in the vicinity of the few health units that had vaccine. Otherwise, vaccination was little practised in Nepal.

Socio-economic and demographic factors played unusually important roles in the development of the programme and in the pattern of occurrence of the disease. Geographically, the country consisted of three horizontal belts (Fig. 15.27) extending across the country: the flat Terai of the Ganges river plain, with a population density ranging from 750 per square kilometre in the east to

fewer than 100 per square kilometre in the less fertile west (Fig. 15.28); the Middle Hills area, with a terrain rising as high as 3000 metres and containing a few broad populous valleys including the Kathmandu valley, which had a population density of almost 1000 per square kilometre and about 5% of the country's inhabitants; and the Himalayan mountains, comprising 30% of the land surface but containing only 5% of the population. Very few people crossed the Nepal-China border, but travel across the Nepal-India border was unimpeded and frequent.

With only 680 kilometres of paved roads and 2 short railway lines (Fig. 15.27), there was little easy communication between the different areas of Nepal, although a network of footpaths connected the 29 000 villages and market centres in which 95% of the population resided. Kathmandu (population in 1971, 150 000) and Biratnagar (population, 45 000) were the only significant urban centres. On the other hand, contacts between the Terai and Kathmandu and India were numerous and were facilitated by the few motorable roads between the two countries.

The Nepalese of the Terai are Hindu and ethnically similar to their Indian neighbours. Many resisted vaccination for religious reasons; temples to Sitalā mata, the goddess of smallpox, were to be found throughout the

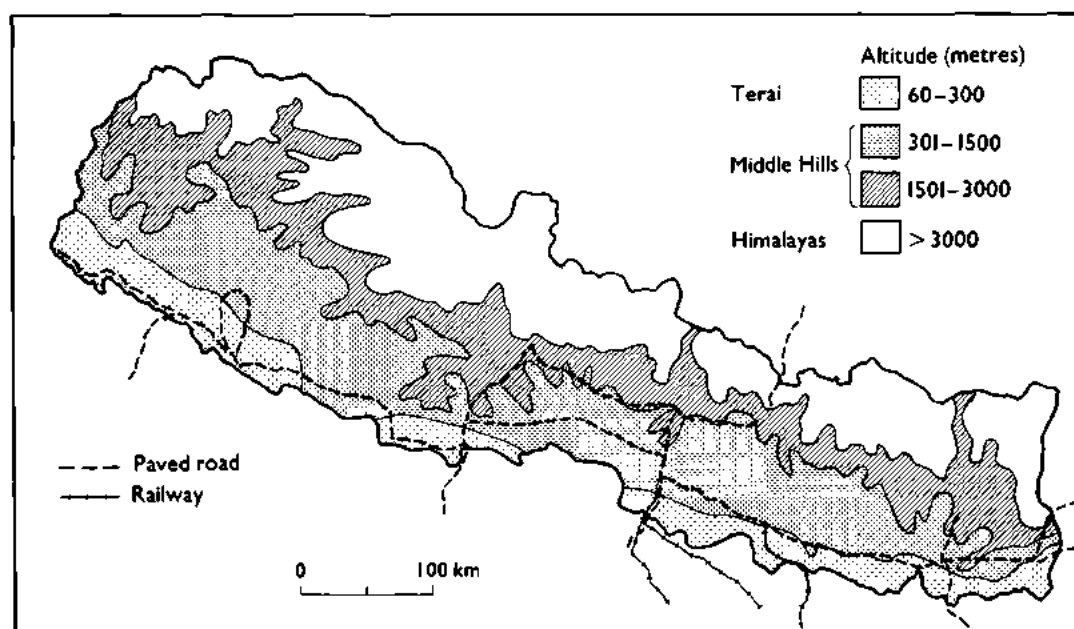

Fig. 15.27. Nepal: physical topography, showing paved roads and railways.

Fig. 15.28. Nepal: population density, by district.

region. The relatively rich agricultural and industrial area of the eastern Terai attracted numerous Bihari and Bengali seasonal migrants, who formed a sizeable proportion of the labour force. Travel to and from the less prosperous western Terai was limited primarily to family visits, and few travelled long distances. Those living in the Middle Hills were predominantly Hindu, but with the exception of some segments of the Newar

ethnic group in the Kathmandu valley most people readily accepted vaccination. Travel to and from the Middle Hills was less frequent than within the Terai, although many moved to the Terai and to India for the winter months. Numerous inhabitants of the Eastern Hills worked on tea estates and as forest labourers in the Indian state of Assam and those in the Western Hills travelled to western Uttar Pradesh and cities of western India for work and trade. In the sparsely populated Himalayas, villages were isolated. To reach most districts from the endemic areas of India required a trek of more than 14 days—longer than the incubation period of smallpox. Because of these factors, smallpox proved to be primarily a problem of the Terai, only 4 outbreaks ever being detected in the extensive northern mountainous areas (SME/77.1, Shrestha et al.).

J.S. FRIEDMAN

Plate 15.18. At times, the roads in Nepal were almost impassable.

#### A Smallpox Control Pilot Project Begins, 1962

A smallpox control pilot project was initiated in 1962 in the 3 districts comprising the Kathmandu valley, which had a population of about 500 000 at that time (WHO/SE/69.10, Singh). With assistance provided by a WHO nurse already employed in another project in Nepal, a house-to-house mass vaccination campaign was begun, utiliz-

ing the multiple pressure method of vaccination and freeze-dried vaccine provided by WHO. As in India, all records were maintained in family registers in which the names of all residents of households were laboriously compiled, revised and updated. The programme was poorly funded, poorly supervised and poorly executed and with the additional impediment of resistance to vaccination progress was slow. A sample survey carried out late in 1964, 2½ years after the programme began, revealed that only 31% of the population had vaccination scars. In 1963, for the first time Nepal began to report cases of smallpox to WHO, but virtually all of them had occurred within the city of Kathmandu. In 1966, a WHO medical officer was assigned to assist the programme, but no effort was made to develop a national reporting system, and until 1968 the programme remained what it had been—an ineffective vaccination campaign confined to the Kathmandu valley. Repeat surveys in May 1967, conducted among various population groups in that area, showed that only 40–65% of the people examined had vaccination scars or the pockmarks of smallpox (WHO/SE/69.10, Singh).

### The Programme Extends Beyond the Kathmandu Valley, 1968

In 1967 the government and WHO agreed on a phased plan to extend the programme zone by zone throughout the country. This commenced the following year with the hope that the last of the zones would be included in the programme by 1972. Additional resources were made available by the government, and WHO provided support in the form of personnel, vehicles and equipment and also covered the cost of petrol (Table 15.35). Staff were recruited, trained and assigned to district offices to serve as "senior vaccinators". During the first 3 months of a new vaccination campaign in a district, temporary vaccinators were hired to vaccinate widely throughout the district. Subsequent vaccination and surveillance were then the responsibility of the senior vaccinator. The family registers were abandoned and multiple puncture vaccination with bifurcated needles was introduced.

The number of districts covered by the programme grew from 3 in 1967 to 15 in 1968 and to 41 by the end of 1970. The number of vaccinations performed increased

10-fold, from 201 000 in 1965–1966 to 2 196 000 in 1968–1969 and to 2 823 000 in 1970–1971 (Table 15.36).

Community leaders and such health staff as were available were contacted and requested to report cases, but the numbers of cases notified remained few: 110 cases were reported in 1967, 249 in 1968, 163 in 1969 and 76 in 1970 (Table 15.37). Although reporting was very incomplete, it is probable that the true incidence in Nepal during these years was not high because the corresponding

incidence in the neighbouring Indian states of Bihar and Uttar Pradesh was low.

### The Programme Strategy Changes, 1971

Early in 1971, a new strategy, unique to Nepal, was adopted and effectively executed by an energetic Nepalese programme director, Dr P. N. Shrestha, and an experienced WHO smallpox adviser, Dr M. Sathianathan, from Sri Lanka, assisted by 2 United States technical officers—veterans of the western Africa programme—Mr Jay Friedman and Mr David Bassett. It was decided to extend the programme as soon as possible to cover the entire country. Forty-five Nepalese district supervisors were recruited and assigned to most districts in the Terai and Middle Hills, and assistant supervisors or senior vaccinators were sent to the other 30 districts, where each worked under the direction of one of the district supervisors. A senior supervisor was responsible for managing the programme in each of Nepal's 14 zones. In 6 districts, responsibility for smallpox eradication was assigned to a newly planned integrated health services project office (Fig. 15.29).

WHO and Nepalese staff decided that the vaccination campaign would be conducted during a single month in the winter of each year, and for this purpose temporary vaccinators (1 for each panchayat, comprising about 3000 persons) were recruited and trained during a 3-day training session. Simple tally sheets replaced the more elaborate record forms. During the remaining 11 months of the year, the assigned permanent smallpox eradication staff, numbering in all

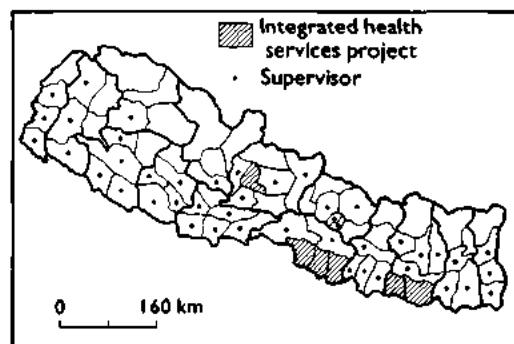

Fig. 15.29. Nepal: administrative divisions and location of district supervisors, 1971.

about 600 persons, travelled from village to village throughout the districts seeking information about smallpox from local leaders, schoolteachers and the personnel of health units. When cases were discovered, the staff were responsible for containment. Four central containment teams were formed to assist in this effort but were soon disbanded, since it proved impossible for them to reach the site of an outbreak before several days—or even weeks—had elapsed because of problems of communication and travel.

Despite the fact that mass vaccination was conducted during the course of a single month each year, the number of reported vaccinations increased to more than 6 million in 1971-1972—a number equivalent to 50% or more of the population—and continued at this level over the next 5 years. Surveys of vaccinal immunity, conducted in 1975 in many of the more accessible areas, revealed that in most of these areas more than 95% of the population bore vaccination scars.

Reporting improved as the programme extended its operations; by early 1973 weekly telegraphic reports were being received from each district regardless of whether any cases had occurred.

Because of the difficulties of travel, responsible district supervisors proved to be the vital element in the programme. They were brought to Kathmandu annually for refresher training and were visited as often as possible in the field by Nepalese and WHO staff, who, beginning in 1972, undertook to visit the site of each outbreak to assess the efficacy of the containment measures. To facilitate travel to the most remote districts, arrangements were made by WHO to permit the charter of a helicopter; it was used on perhaps a dozen occasions during the subsequent 3 years.

**Plate 15.19.** **A:** Purushollam N. Shrestha (b. 1939), the director of the smallpox eradication programme in Nepal from 1971. **B:** Jay S. Friedman (b. 1940), a WHO technical officer, being presented with a certificate of appreciation by the Prime Minister of Nepal, Tulsi Giri.

In 1972, the programme was extended to include all districts in the Terai and Middle Hills—the districts of greatest concern. Because of the isolation of the villages, most outbreaks were readily contained, and by the end of June 1972, transmission appeared to have been interrupted. During the last 6 months of the year, only 5 outbreaks, with 34 cases, were discovered (WHO/SE/74.71, Shrestha et al.); 4 resulted from importations from Uttar Pradesh and 1 from Bangladesh, whose north-western border with India was less than 50 kilometres—merely a day's journey—from Nepal.

However, as epidemic smallpox swept across Uttar Pradesh and Bihar in 1973, increasing numbers of cases began to be imported into Nepal (Fig. 15.30). In all, 43 outbreaks and 277 cases were reported that year, of which 35 outbreaks resulted from importations from India. Twenty-eight more cases occurred in these outbreaks that were not officially notified until 1974. Most of the imported cases had been infected in bordering districts of Uttar Pradesh and Bihar. The sources of the outbreaks included 12 districts in Uttar Pradesh and 9 in Bihar. One infected traveller came from the state of Maharashtra, although he was probably infected while travelling through Uttar Pradesh. All but 4 of the importations occurred in districts bordering on India.

Smallpox did not spread extensively, however. From the 35 importations, second-

dary spread to other villages occurred on only 7 occasions, one of these villages being the source of a further outbreak. The number of cases in each outbreak ranged from 1 to 38 with a mean of 8.3 cases, of which almost one-third (13 out of 43) were single-case outbreaks (Table 15.38).

In November and December 1973, the number of importations began to increase

**Fig. 15.30.** Nepal: importations of smallpox, 1973 and 1974. Each dot denotes one outbreak.

Table 15.38. Nepal: number of outbreaks of smallpox, by number of cases in each outbreak, 1973-1975

<sup>a</sup> Data for 28 outbreaks not available.

and in January 1974, 14 importations were detected, of which 8 were from Bihar and 6 from Uttar Pradesh (Fig. 15.31). The number rapidly increased during May and then abruptly diminished, which was consistent with the seasonal decline in smallpox. In all, 180 outbreaks and 1549 cases occurred, of which 115 outbreaks were due to importations. As was the case in 1973, most of them (106 out of 115) occurred in districts bordering on India, the eastern districts of the Terai being the most heavily infected. In contrast to 1973, when the sources of infection were widely dispersed geographically, 68% of all importations during 1974 came from 5 heavily infected districts in Bihar. These districts, besides being among the most heavily infected in India, experienced severe food shortages in the spring of 1974 and, in consequence, many people migrated to Nepal.

Fig. 15.31. Nepal: number of outbreaks of smallpox, by source, by month, 1973-1975.

In early 1974, WHO arranged for the prompt, reciprocal cross-notification by telegram between India and Nepal of possible sources of infection in each country. Programme staff agreed to investigate every report of this kind and to confirm whether an outbreak had been found. Nepalese staff fulfilled this responsibility well and detected a number of outbreaks not previously known. In India, especially in Bihar, the system operated far less well: with numerous outbreaks and a poorly organized health system, many reports were ignored (WHO/SE/74.71, Shrestha et al.).

The increase in the number of outbreaks in Nepal taxed the resources for surveillance and containment, and a greater number of outbreaks began to result from local spread. Nineteen out of 57 such outbreaks (167 cases) occurred between February and September following 2 importations into the Kathmandu valley. Most were in the Newar ethnic group, who had resisted vaccination for religious reasons, and among whom it was a common practice for the relatives and friends to visit those who were ill with smallpox. Detection was also difficult because families did not report cases and sometimes hid the patients from health officials. Smallpox could therefore spread widely and containment was difficult.

A second problem area was in the western Terai, in which another ethnic group who also resisted vaccination had the custom of granting any wish to a child with smallpox in the belief that the child was possessed by the goddess of smallpox, Sitalā mata. The child's wish was frequently to be taken to see relatives or friends in other villages. In this area, smallpox spread unusually rapidly among groups of villages (SME/77.1, Shrestha et al.).

A third area which proved difficult was a south-eastern district, Morang, which experienced 29 importations in 1974 and 1 in 1975. It was the centre of jute production in the eastern Terai and contained the industrial town of Biratnagar. Numerous migrant labourers from India were attracted to the area and, in the autumn of 1974, because of food shortages in Bihar, many beggars from India arrived there. Quite a few of the migrant labourers and most of the beggars belonged to a tribal group which worshipped Sitalā mata and resisted vaccination (SME/77.1, Shrestha et al.). The last chains of transmission began in December 1974 and

WHO: P. BOUCAS

**Plate 15.20.** Tibetan pilgrims being vaccinated in front of a Buddhist temple at Bodnath in the Kathmandu valley, Nepal.

January 1975, when 21 cases, primarily among beggars, occurred in a large market area, and from there smallpox spread to 6 nearby villages. More vigorous containment efforts were required; thus, in January, watchguards were posted at each infected house, as was done in India. In addition, systematic search and vaccination programmes were conducted over wide areas encircling the site of an outbreak. The system had been in use in many states of India for more than a year but in Nepal, in which the population was sparse, the containment of outbreaks had been less of a problem and, with fewer personnel, it had been impossible up to this time to adopt the Indian methods of containment. With the numbers of outbreaks diminishing both in India and in Nepal, a more elaborate scheme was possible. Resistance to vaccination was usually overcome with verbal persuasion although, on occasion, police accompanied the vaccinators to lend their authority. The number of outbreaks declined rapidly, and on 6 April 1975 the last cases occurred in Nepal.

Data regarding the age distribution of cases are available for 1286 of the 1921 cases which occurred in the period 1973-1975

(Table 15.39). Smallpox in Nepal occurred more frequently among older children and adults than in India. Less than one-third of all cases were in children under the age of 5 years and 29% were in persons over 15 years of age. The fact that more cases tended to occur in the older age groups in Nepal than in India probably reflected lower levels of vaccinal immunity throughout the population as well as a lower level of naturally acquired immunity due to the relative isolation of villages. Although villages in Afghanistan were comparable in their degree of isolation, vario-

**Plate 15.21.** A Nepalese vaccinator at work. The plastic holder for bifurcated needles in the foreground was designed and first made in Pakistan; the vaccine came from the USSR.

lation had been extensively practised there and many persons were immune as a result. In Nepal, however, the procedure had been largely discarded in recent decades.

Only 40 out of 1915 patients (2.1%) for whom data are available had been vaccinated before exposure—a far lower proportion than that reported from India. Several factors could account for this. In India, in which rotary lancets had long been in use, many apparent vaccination scars resulted from sepsis rather than successful vaccination. In Nepal, few had been vaccinated with the

rotary lancet. Moreover, in the vast majority of instances the vaccination had been performed after 1967 so that vaccinal immunity was likely to be at a higher level.

The case-fatality rate was 21.5% (411 deaths among 1915 patients), a figure consistent with observations elsewhere in the Asian subcontinent.

At the time that the last case occurred, a reward of 100 rupees (US\$9.50) was being offered to anyone reporting a case, and later this sum was increased to 1000 rupees. After 6 April 1975, however, no reported case was

confirmed and no further cases were detected in subsequent laborious house-to-house searches.

### Cost of the Programme

The total outlay on smallpox eradication by the government of Nepal and by WHO during 1962–1976 amounted to US\$2 378 982, or just over US\$0.15 per head of population. For the period 1972–1976, approximately 2% of the Ministry's health budget was spent on the programme. The expenditure, however, was low compared with the cost of other programmes such as that for malaria control, on which, in the year 1976–1977 alone, Nepal spent more than US\$4.5 million (SME/77.1, Shrestha et al.).

### SIKKIM AND BHUTAN

East of Nepal in the Himalayan mountains lay 2 small sparsely settled political entities—Bhutan and Sikkim (Fig. 15.32). Bhutan, an independent monarchy, had an estimated population (in 1967) of 987 000, which was concentrated in the central and southern parts of the country and had contact through trade and travel with the inhabitants of Assam, West Bengal and Bihar in India. Between Nepal and Bhutan was the even smaller and less populous Indian protectorate of Sikkim (population in 1967, 196 000), which in 1975 became a state of India. Both areas shared a northern border with China, but few travellers crossed it.

Sikkim and Bhutan were both at risk of smallpox imported from India, although in neither area had it seemed likely that smallpox transmission could be long sustained among the population of the scattered mountain villages. Thus, until smallpox transmission was interrupted in India and Bangladesh, little support was provided by WHO to either Sikkim or Bhutan and, in fact, information about the smallpox situation in both areas was scanty until late in the Intensified Programme. With the interruption of smallpox in India, attention was directed to these and other more remote areas of the subcontinent to ascertain something of the history of smallpox and smallpox control in recent years and to confirm that transmission was not continuing.

Fig. 15.32. Bhutan and Sikkim and adjacent countries.

### Sikkim

Cases of smallpox had been officially reported in Sikkim since 1954. In 1966–1967, 78 cases in all were recorded at a time of high incidence in northern India. After this, no further cases were reported until 1973, when an outbreak of 34 cases occurred in Gangtok, the capital, the first case having been infected in Darjeeling, West Bengal. A second outbreak, of 11 cases, occurred that year in 2 villages along Sikkim's southern border, the source of infection again being West Bengal. No further cases were detected subsequently. Although reporting was undoubtedly very incomplete, the sporadic occurrence of smallpox was characteristic of an area in which importations were rare, and when they did occur, the disease did not spread easily.

Vaccination had been offered at the 4 district hospitals and 27 dispensaries, and the

Table 15.40. Sikkim and Bhutan: number of reported vaccinations, 1967–1975

Year	Sikkim	Bhutan
1967	114 575	35 944
1968	57 879	18 117
1969	71 812	9 029
1970	49 095	8 114
1971	36 832	43 052
1972	39 652	18 518
1973	45 801	57 375
1974	36 331	53 822
1975	28 846	25 599

number of vaccinations relative to population, at least from 1967, was quite substantial (Table 15.40). That vaccinal immunity was comparatively high was confirmed during a vaccination scar survey in November 1975, which revealed that 79% of the population had scars and only 42 of 1495 persons (2.8%) had the facial pockmarks characteristic of smallpox (Basu et al., 1979).

### Bhutan

Information about Bhutan is less complete than for Sikkim. Until 1961 no health department had been established in the country. In 1964, the government created 19 posts for vaccinators, and increased the number to 25 in 1966, when a mass vaccination campaign was begun following an outbreak of 74 cases of smallpox in 1965-1966 in the capital city of Thimbu. The outbreak had begun among Indian and Nepalese workers employed in a road-building project and then spread to the local population. The number of vaccinations reported to have been performed between 1967 and 1975, however, was small in relation to the population of 987 000 (1967 estimate).

After the 1965-1966 outbreak, only 4 further outbreaks were reported. In 1967, 2 outbreaks originating in Assam caused 14 cases. The third outbreak, of 6 cases, occurred in April 1973 in a village near the south-western border with India, the initial case having been infected on a tea estate in West Bengal. The fourth outbreak, near the same border area, occurred in February 1974 and consisted of 3 cases, of which the first had been infected in Assam. Surveys conducted in 1976 to detect individuals with facial pockmarks, as well as interviews with village officials, indicate that other, unreported, outbreaks had occurred although none had produced more than a few cases. This was attributed in part to the fact that the villages

were scattered and isolated, and in part to the sensible traditional practice of isolating the patient and his family at the onset of illness in a place some distance away from the village. In these circumstances, the spread of smallpox was difficult.

Sample surveys conducted in Bhutan in the autumn of 1976 confirmed that vaccinal immunity among children was generally low, especially in the central and northern parts of the country (Table 15.41).

Facial pockmarks indicative of past smallpox were not seen in anyone under 15 years of age in central and northern Bhutan but were observed in 11 children in southern Bhutan. In northern Bhutan, where adults also were examined, only 10 out of 244 persons (4%) over 15 years of age had the facial scars characteristic of smallpox, the youngest being in his late twenties.

In addition to the 11 children with facial pockmarks detected in the village surveys of southern Bhutan, 3 others were discovered during surveys of schools in this area. Nine of the 14 had experienced illness in 1967 or later, and in each instance efforts were made to identify the source of infection; all were traced to India. One had contracted smallpox while living in Allahabad, Uttar Pradesh, before moving to Bhutan. The other 8 became ill in outbreaks resulting from importations (Table 15.42).

### Summary

The surveys confirmed the belief that the continuing transmission of smallpox in these sparsely populated, isolated countries had not occurred recently—even in Bhutan, in which vaccinal immunity was low. The tradition of isolating the patient and his family, observed in Bhutan, undoubtedly contributed significantly to stopping transmission. This custom, interestingly, was current throughout most mountainous areas of Asia, but was much less frequently practised in the lowlands.

Table 15.41. Bhutan: survey of vaccinal immunity and facial pockmarks in children, by age group, 1976

## CONCLUSIONS

From 1961, when India first decided to embark on a national eradication programme, to 1975, when the last case was detected, the programme gradually improved—in the quality of vaccine employed, in the vaccination technique used, in the reporting system, in the extent and intensity of surveillance and containment and, most important, in the quality of supervision. To undertake a national programme in a country so vast, with a population so large and a bureaucracy so complex, was inevitably difficult. To modify and redirect such a programme proved no less difficult. The dimensions of the effort, which involved at least the part-time participation of more than 150 000 field staff and contact with more than 550 million persons, are hard to grasp or communicate.

India's population, in 1967, constituted almost half of the total number of inhabitants of the endemic countries and, indeed, 15% of the world's entire population. The central direction of the enormous national campaign then in progress rested with only 1 medical officer and a small staff of clerks. In the states, of which 7 each had a population of more than 40 million, direction was generally entrusted to a single medical officer, for whom, in most instances, smallpox eradication was but a part-time responsibility. Working in the cities, towns and villages, however, were tens of thousands of vaccinators, basic health workers, family planning and malaria eradication programme staff and many other categories of health worker. Many were responsible, experienced individuals, conscientious about their jobs and willing to work, but they were seldom provided with much in the way of support or stimulus or the necessary supplies to carry out their assigned tasks. New directions or new policies were more often than not impersonally communicated by official memoranda which frequently demanded the impossible

for example: "All persons in the state will be vaccinated cent per cent [100%] during the next 12 months." Vehicles stood idle and refrigerators remained inoperative for want of petrol or a few spare parts because the monetary resources provided had proved inadequate and/or fiscal procedures were so cumbersome as to prevent the disbursement of the funds. Vaccine deliveries were erratic and numerous batches were unfit for use because of the lack of refrigerated storage.

In the opinion of many, the solution to the disappointing level of productivity throughout the health sector was to eliminate special programmes such as that for smallpox eradication and to integrate all programmes into a unified primary health care programme in which each health worker would assume a multiplicity of responsibilities as a "basic health worker". This was the panacea which had been repeatedly proposed by both Indian and WHO expert groups since the 1950s. It was the course of action recommended in 1966 as India's intensive national vaccination campaign drew to a close, with smallpox almost as widespread as it was before the campaign had begun. In a number of states such integrated programmes were started in the mid- and late 1960s but the productivity of the workers was, if anything, even lower than it had been before.

Given the difficult problems and the paucity of senior leaders, the achievements of the smallpox eradication programme between 1967 and 1973 were remarkable. By the summer of 1973, smallpox transmission had been virtually interrupted in the southern states and was declining in the western states. It seemed that a comparatively modest investment in time by senior epidemiologists to help to develop surveillance and containment activities in the other states should rapidly succeed in interrupting transmission throughout India. The deplorable condition of the health services in some of these states, especially Bihar, Assam and Uttar Pradesh, was not then comprehended, nor were the coming disastrous epidemics anticipated. However, the administrative changes which were made in the summer of 1973 had profound consequences in that they permitted the vast resources of health manpower in India to be utilized effectively and gave scope to the imagination and problem-solving abilities both of senior staff and of field workers. With the active support of the Minister of Health and Family Planning and

an adequate complement of senior Indian and WHO staff to travel to the field to explore alternative solutions to problems, to instruct, to assess and to measure results, field staff took an increasing interest in the programme. Knowing what should be done, they themselves sought new solutions. The onerous fiscal constraints were ultimately resolved through the use of the flexible imprest accounts provided by WHO. With the most senior Indian staff, initially Dr Diesh and later Dr Sharma, not only travelling to state capitals but also visiting field staff in districts and villages, the example was set for otherwise desk-bound lower-level supervisory staff to do likewise. By doing so, they motivated and inspired staff at all levels.

The strategy adopted for the programme also played an important role, the country being divided into 3 different areas, with the objective of preventing smallpox from re-establishing itself in smallpox-free states, of eliminating the few remaining foci in states with a low incidence, and of conducting a major offensive in the 4 states with the highest endemicity. Each of the states thus had specific goals and programmes appropriate to those goals. Measurable indices of progress in achieving eradication were important. These were identified first in terms of the numbers of cases of smallpox occurring each week and then in terms of the numbers of outbreaks in which a case had occurred during the preceding 4 weeks. In the last year of the programme, other standards were formulated to measure the quality of surveillance, of containment and of outbreak investigation. With specified and achievable objectives, all personnel could assess progress in their own area, be it a primary health care centre, a district or a state. Monthly meetings and regular surveillance reports served as refresher training, permitting new approaches to be introduced and serving as a stimulus to all concerned.

The problems that emerged after the intensive campaign was launched in the summer of 1973 were far greater than anyone had expected, but the conviction of the senior leadership and the programme's momentum were sustained in the face of often hostile criticism by some senior Indian and WHO officials, natural calamities of flood and famine, civil disorder and strikes, and the inevitable bureaucratic inertia. The programme improved so rapidly that the

transmission of smallpox was interrupted in India less than 20 months after the first search had begun. Because of the quality of the programme and the confidence achieved through assessment of its merits, it was possible only 3 months after the occurrence of the last case to celebrate India's freedom from smallpox on India's Independence Day in August 1975. In no other country up to that time had it been possible to feel so confident so soon. However, over the next 2 years, the programme staff conducted the most elaborate and extensive search programme of any in Asia to confirm for themselves and—just as important—to convince an incredulous world community that India was truly free of smallpox.

What many failed to appreciate was that the achievement was not the product of a special army dedicated to smallpox eradication, but one in which existing health staff of all types participated actively in managing and executing a programme with measurable objectives. When eradication was certified in 1977, only a handful of long-term smallpox vaccinators and a few senior staff remained to be reassigned to other programmes.

As had been expected, smallpox in Nepal, Bhutan and Sikkim reflected the experience in the neighbouring densely populated Indian states. In Bhutan and Sikkim, the only special activities undertaken, aside from routine vaccination programmes, were those concerned with certifying the absence of smallpox. In Nepal, far more populous and epidemiologically more closely related to India, a special programme was required.

The programme of vaccination and later of surveillance and containment in Nepal represented its first national health programme, and one which extended to all parts of this mountainous rugged country. Since travel throughout much of Nepal was of necessity by footpath, and health facilities were non-existent in many parts of the country, district smallpox supervisors played a vital role. With encouragement from national staff and repeated refresher training, most of these local workers responded well to their responsibilities. The first national disease reporting system was established, and vaccination—all but unknown in most of the country in 1967—reached more than 90% of the population within a period of little more than 5 years. It was an impressive achievement, especially in view of the fact that the ratio of programme staff to population was at

best 1 to 20 000. Nepal's successes were different from India's but no less remarkable.

The programme in India was slow to gain momentum and undoubtedly eradication might have been attained far sooner if an adequate complement of well-motivated senior supervisors had been provided at an

earlier stage. In all probability, the greatest catastrophe of the Intensified Programme would have been averted—namely, the 1971 epidemic in the Calcutta Salt Lake Refugee Camp, which led to the reintroduction of smallpox into Bangladesh and to tens of thousands of deaths.

## INTRODUCTION

The Indian subcontinent has long been regarded as the probable place where smallpox originated—its traditional endemic home. It was a disease described in early Indian writings and enshrined both in Hindu religious belief and throughout the country in

temples to the smallpox goddess. Variola major, with a case-fatality rate of 20% or higher, was the only variety of smallpox found in India and, as recently as the 1950s, it is estimated to have killed more than a million persons annually. Many held the view that because of population density, or for other ill-defined socio-cultural or epidemiological

Fig. 15. 1. Bhutan, the states and union territories of India, and Nepal. Many of the most densely populated areas in the region are in the Gangetic plain. In India, Karnataka was known as Mysore until 1973; Arunachal Pradesh was the North East Frontier Agency until 1971; and Sikkim became a state in 1975. Bangladesh was East Pakistan until 1971.

reasons, the eradication of smallpox in India would ultimately prove impossible. This belief had its roots in the behaviour of cholera, which for centuries had been confined to the riverine areas of the Indian subcontinent. In the 1830s, cholera spread across the world in the first of seven global pandemics, only to disappear over time, except from the Ganges river plain (Fig. 15.1). Although cholera was a bacterial disease with wholly different epi-

demiological characteristics, many believed that there were unique, yet unrecognized features of this area which would doom a smallpox eradication effort as certainly as an effort to eliminate cholera.

There were other reasons for pessimism. In area, India was the world's seventh largest country but second only to China in size of population. Of the 1100 million people living in areas which had endemic smallpox in 1967,

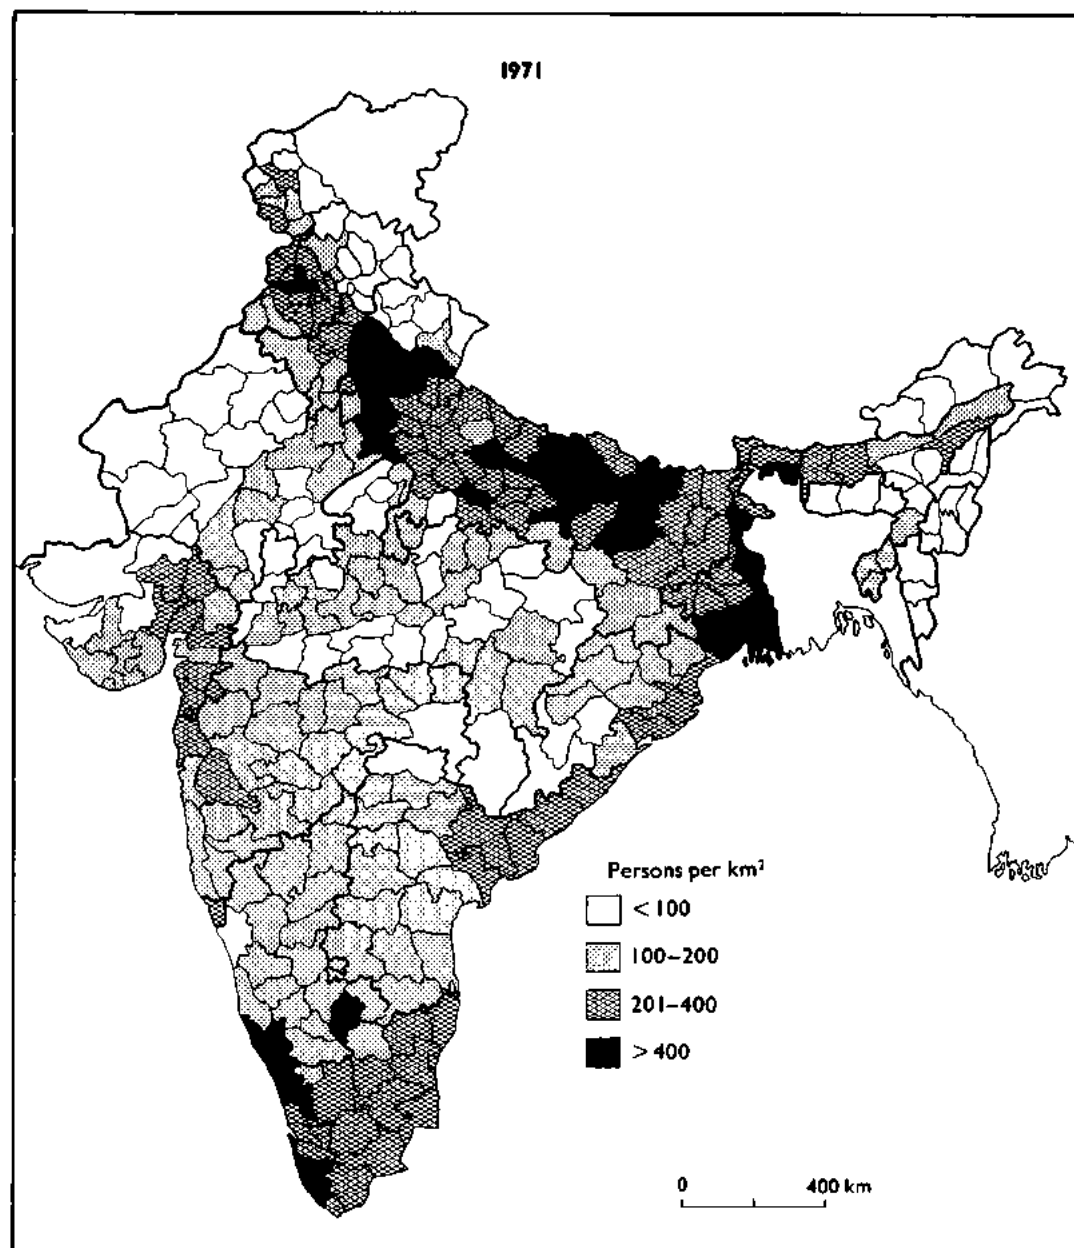

Fig. 15.2. India: population density, by district, 1971.

513 million (47%) lived in India. The most densely populated zone was the Ganges river plain in the north (Fig. 15.2), some 2400 kilometres long and 240–320 kilometres wide. Sharing borders with India and epidemiologically related to it were the 2 small Himalayan mountain kingdoms of Nepal (population 10.8 million) and Bhutan (population, 987 000), and the Indian protectorate of Sikkim (population, 196 000). (Sikkim became an Indian state in 1975.)

A smallpox eradication campaign had begun in India in 1962 (Fig. 15.3) but, despite an intensive and costly effort, smallpox was still widely prevalent in 1967 and substantially underreported throughout the country. A pilot smallpox control programme had been launched in Nepal in 1962, but cases continued to be reported from the only 3 districts which reported at all. Little was known in 1967 about the situation in Bhutan and Sikkim.

In 1967, the meagre resources available to WHO precluded the provision of meaningful support to all endemic countries in Asia. A programme was already established in India, although functioning poorly, and India at that time requested international assistance only to permit the acquisition of equipment for vaccine production. Thus, WHO's assistance in Asia was directed to the less populous endemic countries—Afghanistan, Indonesia, Nepal and Pakistan (which then included East Pakistan, later to become Bangladesh). It was hoped that successful programmes in these countries would eventually permit the release of significant resources in support of the Indian national programme if required. A joint India-WHO team assessed the Indian

programme in 1967 and, subsequently, WHO staff from Headquarters and the Regional Office for South-East Asia in New Delhi held frequent meetings with Indian government staff. Until 1970, however, progress was slow. That year, a WHO-India agreement was signed which provided for WHO support for field activities. During the following 3 years considerable progress was made in the southern and western states but little in the northern, densely populated Ganges river plain. Meanwhile, country after country in Africa, South America, and Asia succeeded in interrupting smallpox transmission. By June 1973, only 5 endemic countries remained, of which 4 were adjoining countries in Asia (Bangladesh, India, Nepal and Pakistan) and the fifth was in Africa (Ethiopia).

In June 1973, Indian and WHO staff decided on an ambitious campaign to involve more than 100 000 local health staff throughout India in a village-by-village search for cases. Such searches would be completed in 7–10 days and would be undertaken monthly in heavily infected areas and less often in areas in which few or no cases were being reported. Outbreaks, when found, would be contained by local health staff assisted by state and district surveillance teams. With this strategy, it was hoped that transmission might be sharply curtailed by January 1974 and perhaps interrupted as early as June 1974. The problems proved far more formidable than had been foreseen. Although the original optimistic target was not met, transmission was interrupted in May 1975, less than 2 years after the special programme had begun—a considerable achievement in so vast a country.

In sheer magnitude and scope, in innovation and adaptation to adversity, in dedication and enthusiasm, in the degree of international cooperation and understanding, the Indian programme from September 1973 onwards was one of the finest endeavours of the global campaign. It is impossible to do full justice to this vast programme in a single chapter. Fortunately, a number of publications describe the overall programme, focusing primarily on its concluding phase. Two books, *The Eradication of Smallpox from India* (Basu et al., 1979) and *The Management of Smallpox Eradication in India* (Brilliant, 1985), are particularly valuable. Special issues of the *Indian journal of public health* (January–March 1978) and *The journal of communicable diseases* (August 1975) also provide important information.

Fig. 15.3. India: number of reported cases of smallpox, by year, 1950–1975.

This chapter includes an account of the closely related and ultimately well-executed Nepalese programme, of which there is no published description. It concludes with such information as is available regarding activities in Bhutan and Sikkim, which experienced only infrequent importations after 1966.

## INDIA

### Background

India's immense size and vast population, of whom more than 80% lived in rural areas, was but part of the challenge. In India, as well as in East and West Pakistan, there was an extraordinary movement of population from place to place for purposes of business and attendance at marriages and funerals. Numerous religious pilgrimages and gatherings attracted huge crowds, sometimes amounting to millions of people. Uncountable hundreds of thousands travelled throughout the country on 10 800 daily trains. The state transport system, including buses and other motor vehicles, alone carried some 10 million passengers (about 2% of the population) each day. Reflecting the extent of internal migration, the 1961 census showed that a third of the population was enumerated outside their places of birth that year; during succeeding years, mobility substantially increased. This was important in smallpox transmission. Often, persons who were exposed to or became ill with smallpox would journey long distances to return to their home villages, disseminating smallpox when they arrived and sometimes in the course of the journey.

Also unique to the Indian setting was a belief among Hindus that attributed smallpox to the wrath of a goddess, called *Sītālā* (*Shitala*) *mata* although known by a number of different names among India's 15 major language groups and 250 regional dialects. It was not surprising that a deity was associated with smallpox, considering the antiquity of the disease and the large numbers of people it afflicted, of whom 1 in 5 died. Its severity was illustrated by the fact that as late as the mid-1800s, 13% of all recorded deaths in Calcutta were due to smallpox, and 75% of blindness in India at that time was attributed to the disease (Rogers, 1944). Some persons resisted vaccination, fearing that it would anger the

goddess. Religious ceremonies in her honour were common at specially dedicated temples as well as in people's homes.

Finally, there were the complexities of the administrative structure. India, a parliamentary democracy, was divided into 21 states and 9 union territories. (In 1975, Sikkim became the 22nd state.) These were further subdivided into 393 districts and 5247 community development blocks (Table 15.1). Of the 575 721 villages enumerated in the census of 1971, approximately 319 000 had a population of less than 500; only 6333 had a population of more than 5000. There were only 4 cities with more than 2 million inhabitants: Calcutta (7 million), Bombay (6 million), Delhi (3.6 million), and Madras (3 million).

At the national level, responsibility for health programmes was shared by the Minister of Health, a political figure; the Secretary of Health, a non-technical administrative executive officer; and a technical Director-General of Health Services, who implemented health programmes. Substantive decisions required the collaborative understanding of all three. In each state the administrative structure replicated the national one. Although there was some variation in the type of organization from state to state, there were district health units in most, directed by a chief medical officer of health (or civil surgeon). In large states, several districts were grouped in divisions and, for each, there was a divisional medical officer. Districts were divided into basic health units termed primary health centres (corresponding usually to community development blocks), which attended to the health needs of 80 000–150 000 people living in 150–350 villages.

### Smallpox in India before 1962

Vaccination had first been performed in India in 1802 and an organized vaccination programme was begun in Bombay in 1827 (Rogers, 1944). By 1868, some type of vaccination programme had been established in all provinces, although little was done in most of the 560 independent princely states, in which about a third of the population resided. With increasing numbers of vaccinations, the numbers of registered deaths from smallpox declined between 1878 and 1937, despite a progressively improving system for the regis-

**Plate 15.1.** The goddess of smallpox has long been worshipped throughout the Indian subcontinent. She is usually portrayed as a woman riding on an ass, carrying a broom in one hand and a waterpot in her other arm. In northern India, she was known as Śitalā mata, śitalā meaning the cool one, and mata meaning mother. Though worshipped primarily by Hindus and Jains, in Nepal she was incorporated in the Buddhist pantheon as Ajima, the mother of Gautama Buddha. Offerings were made at temples dedicated to her and to images in the home; annual festivals were held on her feast day. Beliefs and practices differed from place to place and the goddess was variously considered to have powers to prevent or cure the disease as well as to inflict it.

<sup>a</sup> From Rogers (1944).

<sup>b</sup> United Nations (1985) estimate for 1967.

tration of deaths and a growing population (Table 15.2). Data comparable to those provided by Rogers could not be obtained for the period 1937–1961, but data for 1962–1971 are available—1962 being the year in which India commenced a special national smallpox eradication programme (see below). It is not known how complete the registration of deaths may have been at different times.

However, studies conducted during the early 1970s showed that even then, the number of reported cases of, and presumably deaths from, smallpox represented less than 5% of the cases and deaths that had actually occurred.

Vaccination programmes were gradually extended throughout most of the country and, following India's independence in 1947,

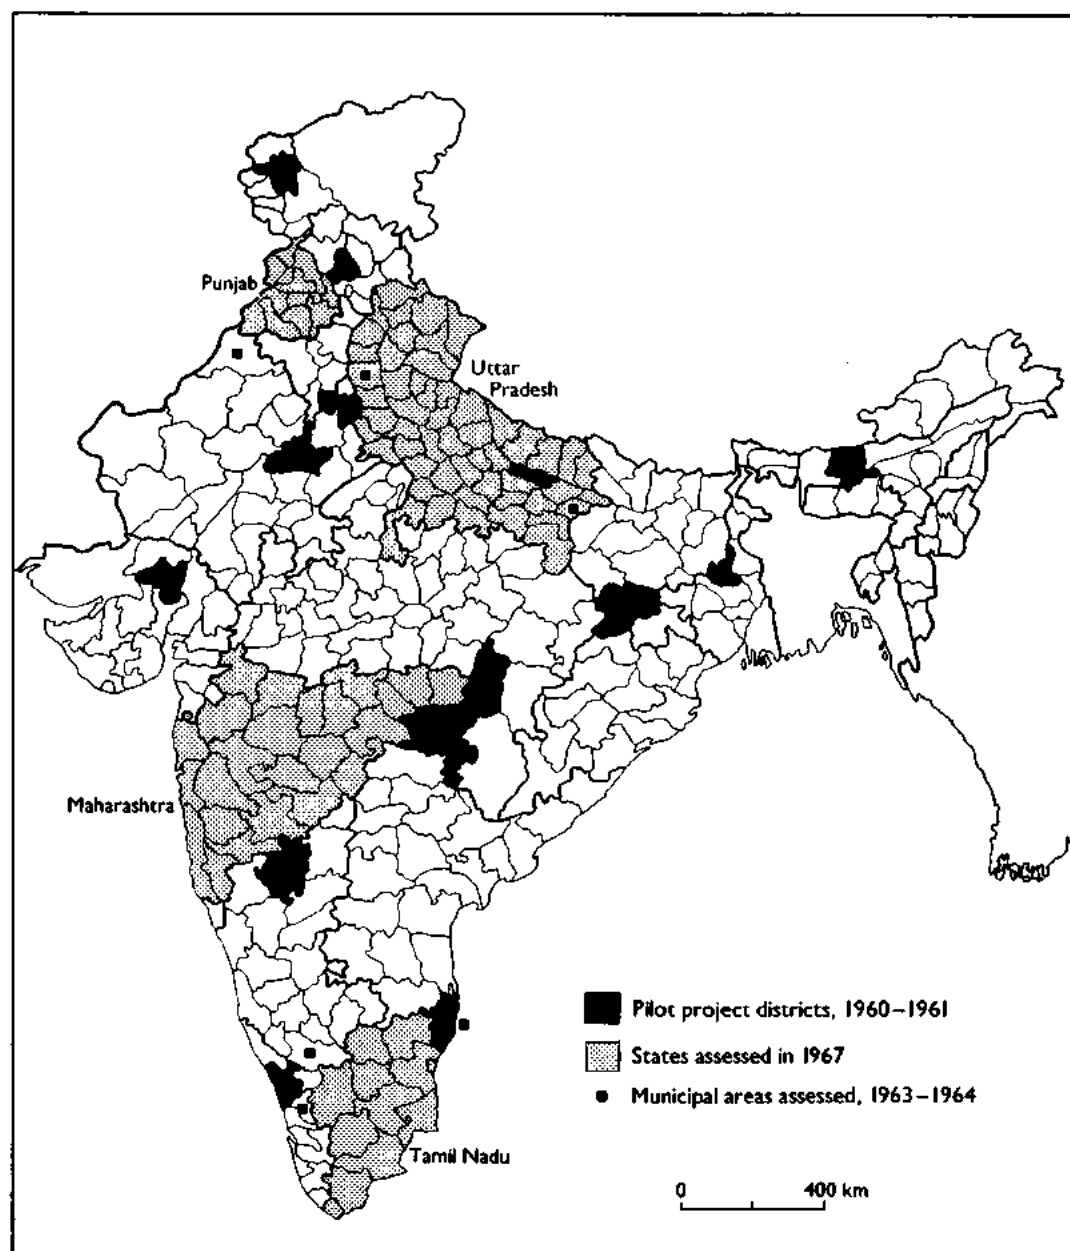

Fig. 15.4. India: pilot project districts for the National Smallpox Eradication Programme (NSEP), 1960–1961; state programmes assessed in 1967; and municipal areas assessed, 1963–1964.

to the remaining princely states. Thermolabile liquid vaccine was the only vaccine available and many of the vaccinations performed must have been unsuccessful. This vaccine was produced in 14 laboratories in 11 different states. As in Pakistan, vaccinators who were recruited and hired by the local administrative organization and termed "local body vaccinators" performed the vaccinations. The programme of vaccination provided only partial control of smallpox, but because vaccination was widely available and variolation was forbidden by law, the latter practice ceased and, by the late 1950s, was no longer a problem in India.

### India's National Smallpox Eradication Programme, 1962

In June 1959, one month after the decision of the Twelfth World Health Assembly to undertake a global eradication programme, an Expert Committee of the Indian Council of Medical Research recommended that a National Smallpox Eradication Programme should be established. The vaccination campaign that resulted was of heroic dimensions and, although failing in its goal to eradicate smallpox, it served to extend vaccination to all but the most isolated villages and created an army of workers and a momentum which provided a foundation for the subsequently successful eradication effort.

Pilot projects were first developed in one district per state to work out methodology and to develop estimates of costs and personnel requirements (Fig. 15.4). The projects began in 1960 and concluded in March 1961 (India, Ministry of Health and Family Planning, 1966).

The essence of the strategy called for a specially recruited team to move systematically from house to house and from village to village throughout a district in an effort to vaccinate or revaccinate not less than 80% of the population. With this proportion vaccinated, it was expected that a sufficient number of persons would be immune so that smallpox transmission would terminate spontaneously. The vaccination team was preceded by enumerators, who listed in a large multi-page register the name of each person along with his or her address, age, sex and previous history of vaccination or of smallpox. One register was compiled for each village or defined area in a city and was intended

to be used during the subsequent 20 years. After enumeration had been completed, the register was given to the vaccination team, which then endeavoured to vaccinate those who were listed. The register was next given to an inspector, who was to check each vaccinee to ensure that vaccination had been successful. Subsequently, local health unit vaccinators (1 for every 50 000–70 000 persons) were assigned responsibility to vaccinate those missed in the mass campaign ("mopping-up vaccination"), to maintain the registers, to revaccinate everyone every 5 years and to vaccinate contacts when cases were discovered. Performance in the pilot projects was poor. In a target population of 23 million, only 12 million (52%) were vaccinated. No evaluation of the programme was conducted nor was smallpox incidence monitored. Nevertheless, as happens only too frequently, the pilot projects were followed almost immediately by the introduction of a national programme.

The USSR offered freeze-dried vaccine, which was largely but not entirely intended to replace the thermolabile liquid vaccine; the United States Agency for International Development made a grant of rupees equivalent to US\$2 million; and UNICEF pledged equipment for vaccine production. Eventually, the USSR provided 650 million doses of vaccine and the USA, between 1961 and 1967, contributed the rupee equivalent of US\$23 million, which had been generated by the sale of foodstuffs provided to India (termed Public Law 480 funds).

Since health programmes in India are constitutionally a state responsibility, the principal administrative direction of the smallpox eradication programme was delegated to the states. Only 2 professional staff provided coordination at the national level. However, because smallpox was considered a national priority, the programme was "centrally sponsored"; the states were reimbursed by the central government for all non-recurring expenditures and for 75% of recurring costs.

The government created 152 units, each of which was expected to vaccinate about 3 million persons in an "attack phase" lasting 2–3 years. Each unit consisted of a supervising officer (usually a physician), a paramedical assistant, 60 vaccinators, 12 inspectors, 12 enumerators and 2 health educators. Each unit was assigned 3 vehicles. In all, more than 13 000 persons were employed, most of whom

### Recommendations for Primary Vaccination in Early Childhood, 1963

The programme's recommendations for primary vaccination were taken from a publication of the British Ministry of Health and distributed in a circular to all administrative staff in 1963. It stated that primary vaccination "should be carried out some time before the age of two years, preferably during the second year" and listed as specific contraindications: "failure to thrive, exposure to infectious disease, septic skin conditions, infantile eczema and other allergic conditions, hypogammaglobulinaemia and corticosteroid treatment" (India, Ministry of Health and Family Planning, 1966). Although perhaps appropriate for the United Kingdom, where smallpox cases were only occasionally imported, the recommendations were inappropriate for India, where many children were exposed to smallpox from birth, where the risks associated with vaccinating most of those with the listed contraindications were much less than the risk of death due to smallpox, and where most vaccinations were performed by scarcely literate vaccinators who could not be expected to recognize many of the conditions noted. Indeed, if all the contraindications had been carefully observed in India, few children would have been vaccinated. Sensibly, the recommendations were largely ignored by most vaccinators, although some did not vaccinate children who were ill with fever or had skin infections. Throughout India, 3 months of age was generally respected as the lower age limit for vaccination. By 1970, a more realistic and appropriate policy had evolved. It called for vaccination from the time of birth and recognized no contraindications except one: vaccinators were instructed not to vaccinate seriously ill persons who might be expected to die over the succeeding day or two and whose death might thus erroneously be attributed to vaccination.

were newly hired and trained. The programmes were launched in 1962 and 1963.

Between 1962 and 1966, 440 million vaccinations were reported to have been performed. It was an impressive number but it did not signify that this many persons had been rendered immune. The first indication of difficulties was observed in New Delhi in the winter of 1963 (Gelfand, 1966). Between December 1962 and May 1963, 346 cases of smallpox occurred in an area in which the number of vaccinations performed was equivalent to more than 80% of the population. Sample surveys conducted in 18 representative areas revealed that, in fact, vaccinations had been given to only 63% of the population and that, of these, 86% had been successful. It was therefore concluded that only 54% of the population had been successfully vaccinated. This discrepancy between the number of vaccinations reported and the number of people actually rendered immune was attributed to a falsification of records and the repeated vaccination of readily accessible groups, particularly school-children. The government was disturbed by these findings and asked India's National Institute of Communicable Diseases to under-

take similar surveys in other states. Five were subsequently conducted in districts which reported that the number of vaccinations performed was equivalent to 80% or more of the population. In operational terms, this meant that the mass campaign "attack phase" had been completed or was about to be completed and the "maintenance phase" was due to begin; during the latter phase the established health services would assume the responsibility for sustaining levels of vaccinal immunity and for controlling outbreaks.

The findings of the National Institute's teams were not encouraging (Gelfand, 1966). The family registers—printed sheets sewn together in a large book—were supposed to include the name of each individual in a defined area and to provide a permanent record of vaccination status. Field assessment showed that many registers had already been lost or were so worn as to be unusable; many names had been omitted; and the clerical task of keeping the registers up to date was overwhelming. It was found, for example, that some individuals who had died as long as a year before were recorded as having just been successfully revaccinated. However in-

effective the family registers may have been, their use continued in many areas until the late 1960s.

The proportion of the population found to have been successfully vaccinated was less than the reported 80% in all districts, ranging from 54% to 73%. Substantially lower levels of vaccination coverage were found in urban districts than in rural areas. Although the numbers reported to have been vaccinated were probably somewhat inflated, the more basic problem was similar to that observed in New Delhi: the most accessible individuals—schoolchildren, for example—were being vaccinated as often as every 6 months, while pre-school children and persons in the lowest socio-economic groups, among whom smallpox was most prevalent, were not being vaccinated at all.

In areas which had entered the maintenance phase of the programme, the National Institute's teams evaluated performance by examining children aged 3–12 months for the presence of a vaccination scar. After the mass campaign, all children on reaching 3 months of age were supposed to be vaccinated by staff assigned to the local primary health centre. In one district, 88% of children 3–12 months old had vaccination scars, but in the remaining districts the corresponding proportions were, respectively, 2%, 9%, 23% and 38%. The National Institute's teams investigated reported cases of smallpox in the maintenance phase areas and in each district they found many other cases which had not been detected.

In view of the fact that the districts evaluated were among the few which had reported that they had achieved the target of 80% coverage, it was apparent that the programme had fallen far short of expectations. An internal document issued by the United States Agency for International Development in November 1964, justifying the programme's continued use of United States rupee funds, stated prophetically: "Eradication of smallpox in India ... is at least 10 years hence ..."

Despite the extensive vaccination programmes, 30 000–40 000 cases of smallpox were reported each year during 1964–1966 (Table 15.3). Because millions had been rendered immune through vaccination, a decrease in the true incidence of the disease is assumed to have occurred, although such a decrease might have been masked by a more complete notification of cases. However, no

specific measures had been taken to improve the reporting system and little is known about its efficacy at this time beyond the recognition that only a small proportion of cases was officially recorded.

Serious deficiencies extended throughout the reporting network at each level responsible for data collection and transmission. In villages, cases of smallpox, as well as of plague and cholera, were supposed to be reported to the primary health centre by the village headman in most states or, in some, by the village watchman (*chowkidar*)—a poorly paid, sometimes illiterate employee of the village council. Some villages submitted reports but many did not. Health workers, assigned to primary health centres, paid little attention to the reporting of smallpox.

An additional problem was that villagers sometimes deliberately hid cases to avoid vaccination, to which they objected for religious reasons or because they feared the painful, infected lesions which so often resulted from the use of the rotary lancet. Some persons who had contracted the disease concealed themselves to avoid being taken forcibly to congested and understaffed hospitals. The cases that came to the attention of primary health centre personnel and district officials were frequently not reported by them to higher authorities because they were afraid of being punished by their supervisors. Many supervisory staff acted on the premise that the occurrence of cases in an area was *prima facie* evidence that the health staff had done an inadequate job of vaccinating the population and so deserved punishment.

At that time, the Central Bureau for Health Intelligence, the national statistical office, simply recorded data, showing little interest in whether the districts and states reported at all. Even the simple task of recording data was confounded by a system, unique to India, which required each district to report each week the number of cases detected according to the week of onset of the cases. This differed from the practice in other countries, in which a weekly report was compiled giving the number of cases of smallpox *detected* that week, irrespective of the date of onset. Thus, instead of receiving and recording one number for each of India's 393 districts, the Central Bureau received new reports of cases for each district extending back weeks or even months. All numbers were entered in a great ledger, past numbers corrected and new

### Vaccination Using the Rotary Lancet

Until the bifurcated needle began to be used in 1970, vaccination was an elaborate and time-consuming ritual. Each vaccinator had a helper who carried a vaccination bag, and the pair proceeded from house to house to identify individuals to be vaccinated. When a candidate was found, the helper unpacked the bag and the following routine, prescribed by the Directorate of Health Services, was followed (India, Ministry of Health and Family Planning, 1966):

1. Check your kit bag to make sure that all the articles are there.
2. Perform vaccinations in a shady place to prevent exposure of the lymph to the sun.
3. Before vaccinating a person, wash your hands thoroughly with plain soap and water.
4. Sterilize both the scoop end and the toothed end of the rotary lancet in water brought to the boil beforehand and kept boiling. Hold the middle of the lancet with your thumb and index finger and dip the two ends in boiling water alternately for a minute each. If quick work is required, hold the two ends of the rotary lancet alternately over a naked flame. After sterilizing the lancet, keep it on a special wooden stand, taking care to see that the two sterilized ends do not come into contact with any other object.
5. Scrub the site chosen for vaccination thoroughly with plain soap and water. Wipe it dry with a sterile swab.
6. Take the vaccine tube from the ice container, unscrew its cap, take the lymph on the scoop end of the rotary lancet, recover the tube and put it aside on a special holder. Place the lymph on the required number of spots, on the outer surface of the middle third of the left upper arm for primary vaccinations, and on the front surface of the left forearm for revaccinations. Place the toothed end of the lancet on the skin through the drop of lymph. Rotate the lancet with gentle and even pressure so as to produce a light circular cut without drawing blood. After making the insertion, rub in the lymph into the scarified area with the scoop end of the lancet. Detain the person for 15 minutes so that the lymph may have time to get absorbed into the skin.

After one or several vaccinations had been performed at a house, the bag was repacked by the helper, and the vaccinator and helper proceeded to the next house.

Vaccinators who failed to permit the lancet to cool sufficiently or who were too vigorous in pressing it into the skin inflicted painful lesions. Because the lancets were often contaminated, the vaccination lesions frequently became septic. The scars which remained sometimes resulted from the growth of vaccinia virus but sometimes were caused by bacterial infection alone. Not surprisingly, many vaccinators were offered money *not* to vaccinate.

Given the routine and the need to record the name of each vaccinee in a large register, it was unusual for a vaccinator to perform more than 25 vaccinations a day. When the bifurcated needle became available, the procedure was greatly simplified and both the special bags and the helpers gradually disappeared. However, the pace of vaccination, by then well ingrained, did not substantially increase.

totals compiled. Similar procedures were followed by district and state statistical offices. However, many of these offices did not forward reports of cases which had occurred several weeks or months previously, considering them not to be of current interest.

The National Smallpox Eradication Programme Advisory Committee held a meeting in November 1965 to decide what should be done when, in March 1966, the attack

phase—the mass vaccination campaign—was scheduled to be completed and the programme throughout the country would enter its maintenance phase (India, Ministry of Health and Family Planning, 1966). The Director of the National Smallpox Eradication Programme, Dr K. M. Lal, expressed optimism that there would be a “further steep fall” in incidence in 1966–1967 but was concerned about the large number of persons who still remained unvaccinated. Because

independent assessments had shown that equating the numbers of recorded vaccinations with the numbers of persons successfully vaccinated was erroneous, it had been decided that a target of 100% vaccination coverage was necessary (a strategy endorsed by a WHO Expert Committee on Smallpox (1964) at Dr Lal's suggestion). Dr Lal doubted that a satisfactory maintenance vaccination programme could be conducted by the existing primary health centre staff, malaria workers, midwives and others. The 1963-1964 assessment had shown this. He favoured a plan which had been suggested to and approved by the Advisory Committee in 1963, whereby 1 smallpox vaccinator would be provided for every 10 000-15 000 persons in rural areas and for every 20 000 persons in urban areas. Such a scheme would be costly and, by any standard, would involve a generous deployment of manpower. Assuming that a vaccinator worked 200 days a year, he could theoretically vaccinate the entire population in a rural area during the space of a year by performing as few as 50-75 vaccinations a day.

Dr Lal and many members of the Advisory Committee were reluctant to end the attack phase with its mass vaccination units until cases had ceased to occur in a district. Various members proposed intervals of up to 3 years as the desirable time for an area to be smallpox-free before it entered the maintenance phase and vaccination was turned

over to basic health staff or local body vaccinators. A special subcommittee was appointed to explore the question further. However, budgetary considerations intruded. The government was forced to decrease expenditure, and the attack phase programme, with its 152 mass vaccination units, was terminated. Special vaccinators for smallpox continued their work in most areas, but in a few, a handful of poorly trained and poorly supervised basic health workers were expected to add vaccination to other tasks.

Meanwhile, vaccine production institutes at Patwadangar, Belgaum, Guindy (Madras) and Hyderabad struggled unsuccessfully to produce the large quantities of freeze-dried vaccine required. By 1966-1967, they were producing only 1.4 million vials (enough to vaccinate about 20 million people). The USSR continued to provide approximately 500 000 vials each month, but even this was not enough. Emergency requests to other governments were regularly channelled through WHO, and several million additional doses were received from the Netherlands, Switzerland and the United Kingdom, but none of these sources could supply substantial quantities since none had laboratories equipped for the large-scale production required. Accordingly, the thermolabile, questionably potent, liquid vaccine continued to be used in a number of states since it was felt that unsatisfactory vaccine was better than no vaccine at all.

Table 15.4. India: numbers of reported vaccinations, percentages relative to population, and numbers of reported cases of and deaths from smallpox, 1962-1976

Year	Primary vaccinations		Total vaccinations		Reported number of cases of smallpox	Reported number of deaths from smallpox
	Number	% relative to population <sup>a</sup>	Number	% relative to population <sup>a</sup>

1971	24 190 000	4.4	91 680 000	16.7	16 190	2 706
1972	26 950 000	4.8	112 730 000	19.6	27 407	5 457
1973	24 840 000	4.4	112 340 000	19.8	88 114	15 434
1974	24 180 000	4.2	123 430 000	21.3	180 003	31 262
1975	19 025 474	3.2	86 718 634	14.6	1 436	176
1976	16 745 086	2.8	66 854 231	11.1	0	0

<sup>a</sup> The percentages provide an index of vaccination activity and are derived by dividing the reported total number of vaccinations performed by the estimated total population (from Basu et al., 1979). The figures do not provide a measure of the proportion of the population newly immunized or whose immunity was boosted. Vaccination was sometimes unsuccessful and some individuals were vaccinated two or more times in a year. Moreover, the reported total numbers of vaccinations performed were sometimes inflated.

The Herculean effort to eradicate smallpox through mass vaccination, launched so enthusiastically in 1962, had all but come to a halt by the time the Nineteenth World Health Assembly, in May 1966, decided to embark on the Intensified Smallpox Eradication Programme. The Indian delegate to the Health Assembly, commenting on the new initiative, pointed out that India would need 180 million doses of vaccine annually, of which it would never be able to produce more than 60 million doses, and expressed the hope that WHO could meet the projected deficit. He cautioned the delegates that unless good basic health services were developed "it would be very difficult indeed to maintain the immunological status temporarily reached" in a mass campaign (World Health Organization, 1966c).

In December 1966, Henderson, who had recently been appointed Chief of the newly constituted Smallpox Eradication unit at WHO Headquarters, arrived in New Delhi to participate in his first intercountry smallpox eradication seminar, attended by representatives from countries in WHO's South-East Asia Region. It was not an auspicious beginning, as India, which then accounted for one-third of the world's cases, announced at the seminar that it had terminated its attack phase and had reverted to a programme of maintenance vaccination.

### The Intensified Smallpox Eradication Programme Begins, 1967

The advent of the Intensified Programme in India found a discouraged staff. Dr Lal, the director of the National Smallpox Eradication Programme since 1962, retired and, because the attack phase had been terminated, was not replaced. This left at the national level only one medical officer, Dr Mahendra Singh, a Deputy Assistant Director-General of Health Services. Although he was overwhelmed by the tasks of giving some sort of direction to the remaining smallpox control activities and of providing the necessary reports to Parliament among many other duties—Dr Singh tried valiantly to stimulate the host of vaccinators distributed across India. He dispatched numerous cables and letters asking state health directors to take action to control epidemics reported officially to him or, as often, through the press. Vaccination targets were established for each

state and those who failed to meet their goals were given forceful reminders. The number of reported vaccinations diminished, however, from 139 million in 1963 and 130 million in 1964 to 96 million in 1967 (Table 15.4). Vaccine distribution was also Dr Singh's responsibility, and a continuing problem because reserves were few and requests to replenish vaccine stocks in state and district offices were often not forthcoming until supplies had been exhausted. Government regulations required that Dr Singh should travel by train or bus, often a 1- or 2-day trip to reach distant and populous state capitals. In each state, there was only one official responsible for smallpox, and he was usually assigned responsibility for one or more additional programmes. The smallpox eradication programme and its still extensive complement of vaccinators laboured under a severe shortage of senior, responsible staff.

### Assessment of the Programme in India, October 1967

In 1967, smallpox incidence rose dramatically, eventually reaching a total of 84 902 cases, more than had been reported in any year since 1958. Concerned by this turn of events, the Indian government agreed that a joint India-WHO assessment team should

**Plate 15.2.** Medical officers at a primary health centre in Maharashtra State. Right: Mahendra K. Singh (b. 1928), a Deputy Assistant Director-General of Health Services, who was the only medical officer at the central level in India's National Smallpox Eradication Programme from 1966 to 1972 and sustained the momentum of the work until additional senior Indian and WHO staff could be assigned. He continued with the programme until the eradication of smallpox in India had been certified in 1977 and was later appointed Director of the Central Bureau of Health Intelligence.

appraise the situation and suggest how it might be rectified. The team's operations were planned and organized by Dr Jacobus Keja, the adviser on smallpox eradication in WHO's South-East Asia Region, and by Dr Singh. In India, an assessment such as this, in which WHO staff travelled to the field, was an uncommon event at that time. Most WHO advisers remained in New Delhi or occasionally visited the more populous state capitals, in which hotels were plentiful. When preparations were being made for the trip, it was discovered that the regional office had in its stores none of the commonly used Indian bedrolls that were needed when travellers stopped at government rest-houses.

The assessment team, comprising 8 senior national health officers and 8 WHO staff and consultants, spent 6 weeks in the field, from 8 October to 19 November. They visited Maharashtra and Uttar Pradesh, two states experiencing epidemic smallpox in 1967, as well as Punjab in the north-west, a state with moderate incidence, and the southern state of Tamil Nadu. The last of these states was of particular interest because of the very few cases reported (263 in 1967) among its population of nearly 40 million.

The observations made by the team are telling, as they provide an overview of the status of smallpox and of the programme in 1967. The team concluded that the programme "is still far from achieving its objective of smallpox eradication in most areas and ... in fact, a very considerable epidemic potential exists in India at the present time." The conclusions of its report are paraphrased below:

#### *Supervision and direction*

● The functions and responsibilities of the National Smallpox Eradication Programme from the central level to the periphery are fragmented

among a variety of independent and semi-independent organizations. There is lack of clarity and definition of responsibilities and objectives at all administrative levels.

● The central directorate is inadequately staffed and has no effective mechanism for exercising clear guidance and direction of the programmes at state and local level. Its functions are limited to the collection from the states of inadequate data regarding smallpox incidence and the number of vaccinations performed, the distribution of imported freeze-dried vaccine, the occasional organization of meetings of state and local programme directors, the distribution of some health education material and liaison with international organizations.

● The states exhibit a great variation in organizational structure. In many, responsibility for the programme is given to a senior officer burdened with many additional responsibilities. With few exceptions, the state directorates act merely as channels for funding, the transmission of instructions and the receipt of periodic reports from the districts.

● In the districts, the district health officer has overall responsibility for the programme as one of many responsibilities. Although as many as 3 paramedical personnel act as assistants, field visits are infrequent, supervision is poor, morale is low, interest in the programme is fading and vaccine is improperly handled and stored. Vaccinators are superintended partly by local administrative bodies and municipal boards and partly by the district staff.

#### *Programme execution*

● Legislation regarding compulsory vaccination varies widely. In some states both primary vaccination and revaccination are required, while in others vaccination is not compulsory. The laws governing enforcement involve cumbersome procedures, and fines are minimal and rarely imposed.

● The plan calls for the vaccination of all newborn infants and other individuals not

Table 15.5. India: vaccinator productivity and salary costs per vaccination performed, 1967

	Number of blocks studied	Number of vaccinations performed per vaccinator per day (range)	Cost per vaccination <sup>a</sup> in rupees (range)
State:			
Maharashtra	10	6.3 (0.5-11.3)	2.42 (13.9-0.48)
Punjab	8	5.7 (0.1-12.7)	3.17 (13.2-0.42)
Tamil Nadu	11	24.5 (6.4-51.6)	0.49 (1.04-0.16)
Uttar Pradesh	19	11.4 (3.1-37.2)	0.94 (8.71-0.20)
Municipality:			
Bombay		14.3	0.47
Madras		8.5	b

<sup>a</sup> Salary costs only—i.e., not including costs of vaccine, supervision, supplies or transport. (In 1967, 1 rupee was equivalent to US\$0.13.)

<sup>b</sup> ... = data not available.

previously vaccinated and the revaccination of everyone every 3 years; it also requires an assessment of "takes" among all primary vaccinees and 50% of revaccinees, as well as entry in the family registers of actions taken. The team concludes that none of the targets is being reached and that records are being falsified in most areas visited.

- The number of *vaccinators* is high (ranging from 1 for every 26 000 persons in Maharashtra to 1 for every 31 000 in Uttar Pradesh) but productivity is low [Table 15.5]. The mean number of vaccinations performed per day ranges from 5.7 in Punjab to 24.5 in Tamil Nadu, but in some blocks the average is less than 1 vaccination per day. Vaccinator salary costs alone average 0.47 rupee (US\$0.06) per vaccination, but in 3 blocks they exceed 7.5 rupees (US\$0.98) per vaccination.

- *Supervision*, except in Tamil Nadu, consists primarily in determining whether or not the vaccinator reports for work.

- *Vaccine* is improperly stored, inventories are inaccurate and refrigerators are frequently lacking or not in working order.

- The number of *reported cases* is estimated to be no more than 10% of the actual number and notification is considerably delayed except in Tamil Nadu, in which reporting appears to be reasonably complete. Many cases which are officially notified to state authorities are not subsequently reported to the national authorities. This deficiency in notification is illustrated by the situation in Punjab, in which state records to date in 1967 showed 1370 cases, of which only 273 had been notified at the national level.

- *Containment* measures are insufficient. For example, in a village in Uttar Pradesh, with a population of 250, 20 cases occurred; after containment, it was found that 20% of the unaffected children remained unvaccinated.

- Contrary to the findings of other reports, *vaccination acceptance* is good and the number of refusals for religious reasons is negligible. For the most part refusals stem from the unwillingness of people to be vaccinated at a time when a serious reaction might interfere with occupational responsibilities. Contributory factors are the tactlessness of some vaccinators, a crude vaccination technique and failure to inform people of the importance of vaccination. The rotary lancets waste vaccine (15 vaccinations are obtained from a vial of 0.25 ml compared with the 25-50 vaccinations obtained when the scratch technique is used); the lancets are difficult and time-consuming to sterilize and produce unusually severe local reactions.

- *Vaccination take rates* are said to be 100%, but assessment from records was possible only in Bombay. The records there show a take rate of 99.7%, but, in fact, failures were being re-

corded only after 3 unsuccessful attempts. The records show a maximum take rate of 77% after a single vaccination but it is probable that the actual take rate is considerably lower.

- The *family registers* everywhere are incomplete and contain numerous errors. They have been abandoned in Uttar Pradesh; in the Punjab and Maharashtra, in which a serious effort is being made to use them, vaccinators spend more than half their time on keeping them up to date.

#### *Levels of achievement*

- Smallpox incidence, the ultimate yardstick for measuring success, is noted to be rising. The total number of cases by the end of 1967 will represent the greatest incidence to be recorded in a decade. Even so, this total will represent 10% or less of the actual incidence.

- Cases are occurring in all age groups, although two-thirds or more in the states assessed are found in individuals under 15 years of age [Table 15.6].

- The proportion of the population reported to be receiving primary vaccination each year is less than 4% in all 4 states. With an estimated birth rate of 4% and many children born in previous years remaining unvaccinated, it is apparent that the number of susceptible subjects is accumulating.

- Sample surveys conducted among individuals under 15 years of age in randomly selected districts of the 4 states and wards of the cities of Madras (Tamil Nadu) and Bombay (Maharashtra) reveal widely different levels of performance [Table 15.7]. Uttar Pradesh has a higher proportion of unvaccinated children than was found in a survey conducted 10 years ago. In contrast, 90% of those in Tamil Nadu and 87% of those in the Punjab have vaccination scars. Vaccination levels in Madras and Bombay are substantially better than in the non-urban areas, a result attributed, in part, to the vaccination of children at birth (nearly 80% of them are born in hospital).

The team offered a detailed series of recommendations prefaced by the statement: "The Central Government should develop a new and long-term strategy to meet the

problem." In brief, it recommended that greater emphasis should be given to case detection and the containment of outbreaks, especially during the summer months, when the incidence was lowest; and that primary vaccination, including the vaccination of newborn infants, should be given priority. An increase in the personnel complement of the national directorate from 1 to 5 professionals and a concomitant extension of their scope of responsibility were also recommended, along with the strengthening of supervision at all other administrative levels. It was suggested that vaccine production should be centralized and financed under national rather than state authority, that the use of liquid vaccine should cease throughout India, that the bifurcated needle should replace the rotary lancet, and that the family registers should be abolished.

### Progress Achieved in the Programme, 1968-1970

The recommendations of the joint assessment team were basically sound but smallpox eradication was not high among the government's priorities. Nevertheless, over the succeeding 3 years, the production of freeze-dried vaccine increased and its quality was improved, many laboratories producing liquid vaccine were closed, the bifurcated needle was introduced, the number of primary vaccinations increased, the vaccination of newborn infants was initiated in several areas, and in some states effective surveillance-containment programmes were conducted.

#### *Vaccine and the vaccination programme*

On the basis of WHO recommendations, Dr Singh stressed in a number of directives

the importance of primary vaccination, and, as from 1968, the proportion of the population reported to have been given primary vaccination increased significantly (see Table 15.4). However, even with the increase, this proportion barely exceeded the birth rate. At the same time, the total number of reported vaccinations declined steadily.

The vaccination of infants at birth was recommended as a national policy. Traditionally, primary vaccination in India had been deferred until children reached at least 3 months of age. Studies begun in 1959 by Dr A. R. Rao in Madras showed that the vaccination of neonates was safe and that systemic symptoms were minimal (Rao & Balakrishnan, 1963). With the liquid vaccine then in use, 80% were successfully vaccinated but, when freeze-dried vaccine and the bifurcated needle became available, this rate rose to more than 95%. It was clear that if vaccinators could vaccinate all children whom they encountered, overall vaccinal immunity would be enhanced. Equally important, higher levels of vaccinal immunity could be achieved in large urban areas, where 75-80% of women were delivered in a hospital or nursing home. Because the high concentration of people in urban areas played an important role in sustaining smallpox transmission, it was hoped that routine vaccination of newborn children in cities might have a significant impact in diminishing incidence throughout the country.

The routine vaccination of neonates began in Madras and Bombay in 1967 and in several other cities of Tamil Nadu in 1968. However, the practice was not enthusiastically pursued in most areas, partly because of the lack of interest shown by the autonomous municipal health officers and partly because mothers were reluctant to let their babies be vaccinated. They had observed in other children

the severe lesions induced by the rotary lancet and had had no opportunity to see the results of vaccination with the bifurcated needle.

From 1968 to 1970, efforts were made to increase the volume and quality of vaccine produced in India and to improve the distribution system and storage of the product. In 1969 the government appointed a central director for vaccine production and distribution, Dr S. N. Ray, and the following year, the 4 vaccine production centres were placed under central government authority and financed by central government funds rather than state funds. This simplified distribution, because vaccine produced in any one of the institutes could then be sent to any state of India without special payments being required. Previously, vaccine produced in each of the state laboratories had been used mainly in that state, while vaccine donated to India, primarily by the USSR, was sent to other states.

Vaccine production in India gradually increased in volume but less rapidly than had been expected. Not until 1974, in fact, did the country become completely self-sufficient (Table 15.8). In part, the delays could be attributed to preoccupation on the part of the director of the Patwardangar laboratory, the principal production laboratory, with the introduction of comparatively new, more elaborate machines for freeze-drying—the so-called shelf-driers. Relatively simple centrifugal freeze-driers were then in use in many countries and when installed in competent laboratories, as in Indonesia and

Kenya for example (see Chapter 11), could be used at full capacity within a year. The director justified the need for the shelf-driers on the grounds that extremely large quantities of vaccine would be required, estimating the need for far greater amounts than had been used during the 1962–1966 mass vaccination campaign. Moreover, he argued that the bifurcated needles, although they used less vaccine and had been adopted in most other countries, would never be acceptable in India. WHO smallpox eradication programme staff, however, foresaw the need for smaller quantities of vaccine, especially if the bifurcated needles could be used, and argued for the purchase of the less complex centrifugal driers. After an impasse lasting almost a year, a staff member of the WHO regional office, who was responsible for providing advice to laboratories, gave approval for the purchase of the shelf-driers, although he himself was not competent in vaccine production. With the promise of purchase of the shelf-driers, the laboratory director gave approval for studies of the bifurcated needle to be undertaken in India (see below). As had been feared, the shelf-driers proved difficult to operate and production increased only slowly but, because of the introduction of the bifurcated needle and the continued provision of vaccine by the USSR, vaccine shortages did not occur.

With an assured supply of freeze-dried vaccine available throughout India, it became possible for the government to insist on the cessation of production of the thermolabile

Table 15.8. India: number of ampoules<sup>a</sup> of freeze-dried vaccine produced each year, 1962–1977, by vaccine production centre, and donated vaccine distributed, 1970–1974

<sup>a</sup> With the rotary lancet, the contents of 1 ampoule were required to vaccinate 12–15 persons. When the bifurcated needle was used, the same quantity of vaccine sufficed to vaccinate as many as 100.

<sup>b</sup> The USSR donated from 5 to 6 million ampoules of vaccine annually beginning in 1962, but data regarding the distribution of this vaccine are not available before 1970–1971.

liquid vaccine. However, closure of the 14 state institutes which produced it proved to be difficult. The central government lacked the necessary authority; one by one, each state and centre had to be visited by officials of the central government and persuaded to cease production. This was finally accomplished in 1970, the last centres being in Calcutta and the eastern states. Even after closure of the production centres, however, problems remained. In several states, the stocks of liquid vaccine occupied all the available refrigerated storage space and, without the sanction of the finance department to destroy the vaccine, programme officers could take no action. Accordingly, in several areas, including Bihar State, in which smallpox was eventually to prove a major problem, stocks of freeze-dried vaccine continued to be stored at room temperature while the obsolete liquid vaccine was kept under refrigeration.

The provision of satisfactory refrigerated storage for vaccine was a continuing problem in other areas as well. The freeze-dried vaccine was supposed to be kept at ambient temperature for not more than 30 days but could be stored almost indefinitely at temperatures of 4 °C or less. Because, for reasons of logistics, most vaccinators could obtain vaccine supplies only once a month, it was important to ensure that vaccine stored in district offices, as well as in the state and national depots, was kept under refrigeration. Satisfactory storage at state and national distribution centres was gradually achieved through the provision of refrigerators by UNICEF and WHO and through the use of other facilities such as cold-rooms normally used for the storage of fruit and vegetables. In the districts, however, satisfactory storage was uncommon. Although virtually all district offices were provided with refrigerators for the storage of drugs and vaccines for a variety of programmes, few were maintained in working order. For example, as late as 1975, 85% of the refrigerators in district offices in Uttar Pradesh were found to be inoperative. Fortunately, as tests of vaccine showed, much of the vaccine produced in the USSR and India maintained levels of potency adequate for primary vaccination even after 3-4 months at high ambient temperatures (Sehgal, 1974; Sehgal & Ray, 1974).

The assessment team had also recommended that at least one-third of all batches of vaccine produced and tested in the separate

laboratories should be independently tested by a national vaccine control laboratory and that the results should be confirmed by a WHO smallpox vaccine reference centre (National Institute of Public Health, Bilthoven, Netherlands). In 1969, an Indian central control laboratory was established at the National Institute of Communicable Diseases, New Delhi, although it was not until 1972 that the laboratory actually monitored the recommended number of batches. In 1969, some batches of vaccine also began to be sent to the WHO reference centre for testing. During the period 1969-1976, of the 241 batches tested by WHO only 9 (3.7%) were found to be substandard (Basu et al., 1979). Although these data would suggest a consistently high level of satisfactory production, it must be noted that all batches dispatched to WHO had been determined, first by the production laboratory and then by the central control laboratory to be completely satisfactory. The producers and the central testing laboratory found a much higher proportion of batches of vaccine to be of inferior potency or stability or unacceptably contaminated with bacteria. Some such batches were destroyed but, in the first few years, most were distributed anyway because vaccine was in short supply. Properly, it was considered preferable to use substandard freeze-dried vaccine than to use liquid vaccine or to have no vaccine at all. No compilation of data on vaccine quality is available, but it was known that the Hyderabad and Guindy laboratories both had persistent difficulties in producing satisfactory vaccine. However, together they accounted for less than one-fifth of all vaccine distributed in India and most of the vaccine they produced was distributed to states in southern India in which health services were generally better and smallpox incidence was lower.

The improved quality of vaccine and a better storage system undoubtedly resulted in a higher proportion of successful vaccinations in the field, although no data are available to substantiate this.

#### *Introduction of the bifurcated needle*

The bifurcated needle had been tested by WHO in late 1967 and early 1968 and was rapidly made available throughout most countries by the middle of 1968. In India, however, the traditional rotary lancet had

been in use since before the turn of the century and a number of prominent senior health authorities as well as the director of the vaccine production laboratory in Patwadangar resisted the introduction of the new instrument. They argued that it would produce fewer successful vaccinations, that vaccinators would find it too difficult to use, and that the population would resist vaccination with an unfamiliar device. Finally, it was agreed that comparative studies of the two instruments would be undertaken by the National Institute of Communicable Diseases and the Central Health Education Bureau (WHO/SE/70.16).

In 1969, the National Institute assessed the efficacy of the two techniques (Pattanayak et al., 1970). In one study, previously vaccinated children were vaccinated on one arm with the rotary lancet and on the other arm with the bifurcated needle. Vaccines of three different levels of potency were employed. The results showed that the bifurcated needle had a clear-cut advantage over the rotary lancet (Table 15.9).

Comparative data derived from a study of a small number of children given primary vaccination showed similar results. It was found that vaccinators readily learned the new technique and used it successfully.

During the same period, the Central Health Education Bureau investigators assessed the acceptability of the new technique, with surprising results. Persons in 5 villages were vaccinated with the bifurcated needle, but they were given no explanation about the new device. One week later, the vaccines were examined to determine the proportion with successful vaccinations and were interviewed about the new technique. All those given primary vaccination, and 79% of those who had been revaccinated, had successful takes. As the investigators noted, "surprisingly, few realized that the technique applied was different from the customary rotary lancet method" (WHO/SE/70.16). With

these results, the needle was accepted by the national health authorities for use in India.

Needles were provided by WHO in large numbers and, by late 1969, they were in wide use in many states. However, the adoption of the new technique required that a decision should be taken separately by each state and municipality, and some were not persuaded. Not until 1971, for example, were the needles used in the states of Uttar Pradesh and Bihar. In many municipalities, vaccinators continued to use the rotary lancet until late 1973, when municipal smallpox eradication staff were brought under state jurisdiction.

The use of the bifurcated needle, however, brought a curious and unforeseen administrative problem. Auditors in India continually scrutinized the number of vaccinations performed in an area and compared it with the number of vaccinations reported in order to detect wastage. The vials of vaccine containing 0.2 ml allowed for only 15 vaccinations if the rotary lancet was used. With the bifurcated needle as many as 100 vaccinations could be performed with the contents of one vial, but in practice, an average of only 40-50 vaccinations was achieved because whatever reconstituted vaccine remained at the end of the day was supposed to be discarded. Although, in fact, more vaccinations were performed per vial supplied, the auditors calculated that each vial should now yield 100 doses of vaccine. Their assertions that vaccine was being wasted were to plague smallpox eradication staff throughout the rest of the programme.

#### *Sample surveys to determine vaccination status*

In 1969, the technique for vaccination scar surveys which had been developed in Afghanistan (see Chapter 14) was introduced into India. Through such surveys it was hoped that responsible officials would identify for themselves deficiencies in their vaccination programmes and correct them.

Table 15.9. India: results of simultaneous revaccination of children with the rotary lancet and the bifurcated needle

Vaccine potency (pock-forming units/ml)	Number of children	Rotary lancet	Bifurcated needle
		Number (%) with satisfactory response	Number (%) with satisfactory response
$1 \times 10^8$	84	22 (26)	47 (56)
$5 \times 10^7$	82	10 (12)	29 (35)
$1 \times 10^7$	81	10 (12)	26 (32)

The simplified methodology for scar surveys, using a cluster sample technique, was enthusiastically received in many states and numerous surveys were undertaken, some of which were state-wide. Not all the surveys were well designed, but the results consistently revealed a remarkably high proportion of vaccinated persons. The surveys showed that vaccination scars were borne by 92-99% of individuals in the age group 5 years and above; by 78-92% of those aged 1-4 years; and by 10-60% of infants under 1 year. Although the results were dutifully compiled and reported, few used the data constructively to identify populations or areas in which vaccinal immunity was low and to improve performance in such areas. The idea of assessing vaccination status in this way was reasonable but, in retrospect, the approach was probably counter-productive in that it served to reinforce the notion that mass vaccination was the principal foundation of the programme, rather than surveillance-containment measures.

#### *The decline in smallpox incidence*

Between 1967 and 1970, the reported number of smallpox cases fell dramatically—from 84 902 to 12 773, the lowest total ever recorded in India. Both government and WHO staff recognized that this reflected, at least in part, the normal periodic fluctuations of smallpox. Peaks in smallpox incidence in India normally occurred every 4-7 years, a periodicity extending back many decades. The peak in 1967 occurred just 4 years after the peak in 1963, which had been preceded, 5 years before, by the peak in 1958. This pattern was said to occur as a result of the gradual increase in the number of susceptible persons because of the waning of immunity in the population at large and the addition of susceptible newborn children. It was believed that when a sufficient number of susceptible persons had accumulated, an epidemic would ensue which would diminish this pool of susceptible individuals and thus the ease with which smallpox could spread. Following the epidemic, smallpox incidence would again decline. The decrease in the number of reported cases between 1967 and 1970 was thus not unexpected, but because the incidence had fallen to such low levels, some government and WHO staff were both optimistic and, to a certain extent, unduly satisfied with progress in the redirection of

the programme. The archaic notification system, with its delays in reporting, only served to reinforce this optimism. By mid-January 1971, for example, only 8026 (63%) of the 12 773 cases eventually recorded for 1970 had been reported to the Central Bureau for Health Intelligence.

#### *Southern India, 1967-1970*

The decline in smallpox incidence between 1967 and 1970 was especially notable in the 6 states and 5 union territories which formed the entire southern part of India. This area had a population in 1967 of 196 million (38% of the national total). The number of cases fell from 42 633 in 1967 to only 795 in 1970. Many districts reported no cases in that year (Fig. 15.5) and none was detected in the entire state of Tamil Nadu (population, 41 million) (Table 15.10).

In part, this decline was attributable to a generally more developed health service structure, especially in the states of Kerala and Tamil Nadu and, in consequence, a better execution of the mass vaccination campaign. It was also associated with the development of an effective surveillance-containment programme—first in Tamil Nadu and later in parts of Andhra Pradesh.

To evaluate the applicability of surveillance-containment in India, it was decided in 1968 to investigate and contain all outbreaks in Madras, the capital of Tamil Nadu, and subsequently in the state itself, employing a surveillance team directed by Dr A. R. Rao, then Health Officer of the Madras Municipal Corporation. Support for this operation was provided by the Indian Council for Medical Research and WHO (WIIO/SE/68.6 and WHO/SE/68.7, A. R. Rao). Dr Rao, for many years the Director of the Madras Infectious Diseases Hospital, had conducted extensive investigations into the clinical and epidemiological behaviour of smallpox (Rao, 1972). He was an ideal person for the task and interested in taking up the challenge.

Smallpox incidence in Tamil Nadu had declined sharply, from 8901 cases in 1963 to only 263 cases in 1967, of which 38 cases had been reported by the Madras Municipal Corporation. The joint India-WHO assessment team (1967) believed that reporting was better in Tamil Nadu than elsewhere in India and, if indeed there were as few cases as notifications suggested, it should be possible to stop transmission with a comparatively

modest outbreak containment programme. If successful, it would serve as an example for other states in India.

Between January and June 1968, the season of highest smallpox transmission, Dr Rao investigated 13 outbreaks in Madras, which were detected when patients were brought to the hospital or when fatal cases were registered at the burial grounds. The source of 7 outbreaks could be traced, 6 of them coming

from adjoining states. Eight of the index cases were hospitalized within 10 days of onset and none of them spread the disease. Five of the infected persons were hidden at home and, before discovery, 8 second generation and 4 third generation cases occurred. However, the total number of cases was small and, as Dr Rao emphasized, smallpox did not spread rapidly in this population despite its high density and the season of the year. In mid-

Fig. 15.5. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1970.

<sup>a</sup> No cases were recorded during this period in the union territories of Andaman and Nicobar Islands, Lakshadweep and Pondicherry.

<sup>b</sup> Became the state of Karnataka late in 1973.

June, the team began to extend its activities beyond the boundaries of the city. The investigation of a case brought to the hospital from a village 24 kilometres away revealed an outbreak of 44 cases in 5 villages. The outbreak had begun in January, when migrant workers returned from the neighbouring state of Andhra Pradesh. As in the city, smallpox had spread surprisingly slowly, suggesting again that outbreaks might be readily controlled. Between July 1968 and June 1969 only 2 additional outbreaks were found in all of Tamil Nadu: one comprised 6 cases imported from Madhya Pradesh State, and the other involved a single patient who had been infected in Gujarat State (WHO/SE/70.19, A. R. Rao). Transmission in Tamil Nadu had been interrupted less than 6 months after a single surveillance team had begun its work; after May 1968 the state remained smallpox-free except for importations.

The Madras team had little to do and so, in October 1969, with the agreement of the authorities in the neighbouring state of Andhra Pradesh (population, 43 million), Dr Rao investigated outbreaks in coastal villages 160 kilometres north of Madras. In all, he documented more than 200 cases in the poorly vaccinated population of a group of fishing villages (WHO/SE/70.17, A. R. Rao et al.). This, in turn, stimulated surveillance activity on the part of the state authorities of Andhra Pradesh. The number of cases in Andhra Pradesh diminished from 7951 in 1968 to 1893 in 1969 and to 358 in 1970. However, transmission persisted, primarily among the fishermen and their families, who migrated seasonally from this area northwards to Orissa State.

The success of surveillance and containment measures in both Andhra Pradesh and Tamil Nadu was dramatic, but, despite Dr Rao's presentations at subsequent national and international meetings, little notice was taken of the achievement. The state smallpox eradication programme officer who accompanied Dr Rao to the meetings rightly noted that the vaccination campaign in Tamil Nadu had been exceptionally well executed, but he argued that it was for this reason, and not because of the surveillance-containment activities, that transmission had been interrupted there. Authorities in other states dismissed the attainment as not surprising in the generally more prosperous southern states and of no applicability to most of the rest of India.

#### *Western India, 1967-1970*

Although progress in southern India gave cause for optimism, the number of reported cases of smallpox doubled in the western state of Gujarat (population, 27 million), increasing from 3403 cases in 1967 to 7654 in 1968. The epidemic continued into 1969, when 6284 cases were recorded—i.e., one-third of all cases reported in India (Table 15.11) and, in fact, almost one-fifth of all cases reported throughout the world.

WHO proposed to the government of India that a team should visit Gujarat to assess the situation. The government agreed, albeit reluctantly, to a 1-week field trip. Since the 1967 India-WHO assessment of the programme, field visits by WHO Regional Office staff, although resident in New Delhi, had been discouraged. It was the government's view that WHO staff could

Table 15.11. Western India: number of reported cases of smallpox, 1967-1970

contribute little to a programme that was directed by a national staff who had been engaged in eradication since 1962. Field visits by national staff were likewise uncommon, Dr Singh rarely being able to leave New Delhi because of his innumerable responsibilities. Moreover, his authority was circumscribed because the responsibility for programme execution rested primarily with the states.

In April 1970, a 3-man team, comprising Dr Andrzej Oles, from the WHO Regional Office for South-East Asia, Dr Singh and Henderson, visited Gujarat State and its capital, Ahmedabad (population, 1.7 million). The epidemic in Ahmedabad was considered by local staff to have begun in November 1969 and, to combat it, 150 temporary vaccinators had been hired to supplement a staff consisting of 1 supervisor (medical officer), 39 vaccinators and a 6-man "flying squad". This provided 1 vaccinator for approximately every 9000 persons. The hiring of large numbers of temporary vaccinators without additional supervisors was a common response throughout India to epidemic smallpox. Between January and March 1970, more than 360 000 people had been vaccinated but the number of reported cases continued to increase. The Deputy Director of Health and Medical Services, Dr G. J. Ambwani, had done a commendable job in improving the facilities for vaccine storage and distribution and in introducing the bifurcated needle. Vaccinal immunity was found to be high in all areas which the team visited. The containment of outbreaks was prompt but poorly executed. The team found many additional unreported cases and in none of the outbreaks had an effort been made to identify the source of infection and, thereby, additional outbreaks. Although local

civil authorities were responsible for case reporting, almost all the cases were reported by vaccinators.

More disturbing was the discovery that the large numbers of cases reported were not reflected in reports to the national authorities. It was found that the Central Bureau for Health Intelligence had recently informed state statistical sections that it wanted a final report from all districts within 3 weeks of the notification of an outbreak. In Gujarat, this was interpreted to mean that any additional cases that were found after this period or any cases that had experienced the onset of illness more than 3 weeks previously should not be reported to the Central Bureau. The cases were, however, recorded by the state's smallpox eradication programme office. Not only was the epidemic in Gujarat of a far greater magnitude than had been suspected, but the discovery that this new policy had been adopted led to the suspicion that India's remarkable decline in incidence might possibly be an artefact caused by a reporting system distorted by misguided or misunderstood directives.

The team concluded that cases were occurring predominantly among a small, unvaccinated segment of the population, amounting to not more than 5-10% of the total, primarily in slum areas and among migrant labourers.

After just 5 days' work in the field, Dr Ambwani realized that he had not previously understood the surveillance-containment strategy and promised to implement such a programme forthwith. Working with the state smallpox eradication programme officer, Dr S. D. Verma, he was remarkably successful. The numbers of cases declined rapidly and in June 1971, only 14 months after the team's visit, transmission ceased.

D. A. HENDERSON, 1970

**Plate 15.3.** Members of an Indian/WHO team to assess the smallpox epidemic in Gujarat State in April 1970. Left to right: Andrzej J. Oles (b. 1923), an epidemiologist with the WHO Regional Office for South-East Asia; Mahendra K. Singh; and G. J. Ambwani, Deputy Director of Health and Medical Services of Gujarat State.

Other cases occurred later but they were traced to importations from other states. The success in Gujarat suggested to both senior Indian and WHO staff that if states were given modest assistance to foster surveillance-containment programmes, these results might be replicated elsewhere. Unfortunately, Gujarat, like Tamil Nadu, was to prove an exception.

The team returned to New Delhi encouraged by Dr Ambwani's interest in and responsiveness to the surveillance-containment strategy but now less confident that the remarkable decline in the number of reported cases was real. A recommendation was made that the reporting system should be changed but this was vigorously resisted by the director of the Central Bureau for Health Intelligence. Thus, the programme continued, its personnel less certain of the true incidence of smallpox but now placing increased reliance on data provided by state eradication programme officers rather than on official government statistical reports. However, because the quality of the programme officers varied greatly from state to state and because the Central Bureau's directives were variously interpreted by officials at different levels, it was difficult to know what the different sets of numbers really meant without field visits to every state—and no staff were available to undertake such visits.

Yet another disturbing observation was made in the western states in the spring of 1970. It began to appear that smallpox might be moving as an epidemic wave in a clockwise direction around India. In 1967, immediately before the 1968–1969 Gujarat epidemic, Maharashtra, the state immediately to the south, had reported especially severe epidemics. That year, it had recorded 27 961 cases, one-third of all cases reported from India. The number dropped to 3173 in 1968 and to 1411 in 1969. In the spring of 1970, the states of Rajasthan and Haryana, immediately to the north of Gujarat, began to experience major epidemics.

This had not been expected. Since the 19th century, major epidemics in the Indian subcontinent had been observed to occur every 4–7 years, but the periodic fluctuations had been thought to take place more or less simultaneously throughout the country. The wider availability of vaccine had not altered this pattern. That the periodicity had persisted until 1962 was understandable because intensive and widespread vaccination had been conducted during and immediately after epidemics, but as smallpox waned so did interest in vaccination. However, it was quite unexpected that the intensive ongoing national vaccination campaign begun in 1962 had not prevented the 1967 epidemic. To explain this recurrence, it was suggested that many states had not conducted effective

campaigns, and because much of the vaccine used had lacked potency, the large pool of susceptible persons had not significantly diminished. Between 1967 and 1970, however, most of the vaccine reaching recipients was believed to be fully potent and because the number of primary vaccinations had substantially increased, the opinion was held that India should not again experience a major epidemic year. Thus, the recurrence of epidemic smallpox, apparently moving in a clockwise direction around India, was totally unexpected but a critical factor in the formulation of subsequent strategy.

In 1970, senior national government staff began to take a greater interest in the smallpox eradication programme. Epidemic areas in Haryana and Rajasthan abutted on New Delhi, the national capital. Reports of the outbreaks appeared in increasing numbers in New Delhi newspapers, and members of Parliament expressed concern through "call-attention" motions, obliging the government to give an account of what was being done.

The Gujarat team had concluded in its recommendations to the government: "... of greatest importance ... is the need to augment the staff at state level to provide leadership to the programme and to develop and coordinate, by active field work, the very critical surveillance-containment activities." WHO proposed to the government that 4 WHO epidemiologists should be recruited to work as advisers with state programme officers. One would be assigned to Rajasthan, in which smallpox incidence was rapidly rising; one each would be allocated to Uttar Pradesh and Bihar, the two densely populated states comprising most of the northern Ganges river plain, and, if assumptions regarding the clockwise movement of epidemic smallpox were correct, the next to experience major epidemics; the fourth epidemiologist would be assigned to work with state programme officers throughout the southern states in an effort to interrupt transmission in this vast area. Dr Singh, meanwhile, would plan to work with programme officers in the small neighbouring states of Haryana, Punjab and Himachal Pradesh as well as the Delhi Municipal Corporation.

The Director-General of Health Services and the Secretary of Health were initially of the opinion that 2 advisers would suffice but ultimately agreed to 4. On 9 September

1970, an agreement was signed by the government and WHO which committed WHO to provide: (1) 4 epidemiologists and 3 short-term consultants for 3 months each in 1970 and 1971, plus the costs of their travel; (2) vehicles and other supplies; and (3) funds to pay salaries, travel and per diem "for additional personnel employed full-time in smallpox units at the national and state levels up to the limit of Rs. 1 125 000 each year" (US\$146 250). In 1970, WHO support to the programme for the first time exceeded US\$100 000. During the succeeding 7 years, more than US\$11 million would eventually be provided, most of which represented contributions from the government of Sweden (Table 15.12). Additional funds were allocated to the WHO Regional Office for South-East Asia, which as the Indonesian programme concluded, began to devote more time to the programme in India.

#### The Foundations are Laid for the Intensified National Campaign, 1971-1973

From 1971 until the summer of 1973 the programme gradually evolved and, in doing

<sup>a</sup>Expenditures by the central government (1965-1969) and state governments (1965-1972) are estimates. Of funds expended by WHO between 1974 and 1977, US\$8.1 million were provided by the Swedish International Development Authority.

<sup>b</sup>Excludes the estimated value of vaccine provided between 1965 and 1974, which amounted to 701 million doses from the USSR and 5 million doses from WHO.

<sup>c</sup>Value of contributions in cash and in kind from Tata Industries (US\$600 000), USA (US\$402 000), UNICEF (US\$380 000), and OXFAM (US\$100 000).

**Plate 15.4.** A: Alberto M. Monnier (1914–1979), an epidemiologist, served as the WHO smallpox officer in Rajasthan State from 1971 to 1976. B: Viatcheslav A. Moukhopad fulfilled the same role in Uttar Pradesh State from 1971 to 1976.

so, laid the foundations for the intensified national campaign, termed "Smallpox Zero", which began in the autumn of 1973. A closer working relationship was established between the government of India and WHO; the bifurcated needle replaced the rotary lancet in all but a few municipal corporations; the use of liquid vaccine ceased completely; larger quantities of good-quality freeze-dried vaccine produced in India became available; the reporting system was changed; and a procedure for the detection of cases was elaborated.

WHO recruited 2 new regional smallpox advisers, for what was then called the Regional Epidemiological Surveillance Team, as well as 4 epidemiologists for assignment to India. Dr Nicole Grasset, a French virologist and epidemiologist, became the regional adviser in 1971, replacing Dr Keja, who had been transferred to Indonesia. She had worked previously in smallpox and measles control activities in eastern Nigeria and had proved to be a charismatic leader. She was joined in the regional office in 1972 by Ježek as the second regional adviser. Although they were responsible for smallpox eradication activities throughout the South-East Asia Region, much of their work was to be devoted to the programmes in India and Nepal. The 4 epidemiologists for the programme in India were assigned to the states. Dr Alberto Monnier, a Mexican epi-

demologist who had been with the Indonesian smallpox eradication programme, began work in Rajasthan in January 1971 and Dr V. A. Moukhopad, a Soviet epidemiologist, arrived a month later to begin work in Uttar Pradesh. That summer, a Czech epidemiologist, Dr Vladimir Zikmund, began work in the southern states. Another epidemiologist reported for duty in Bihar during the summer but stayed only 6 months before resigning. At that time, the post in Bihar was felt to be the least critical, since the available data for 1971 showed smallpox was then concentrated in the north-western part of the country (Fig. 15.6), geographically distant from Bihar. A principal problem in Bihar, as well as in the other states, was the stipulation that each state should provide a vehicle for each adviser and cover the costs of its operation. Rarely before had WHO staff been assigned to work at state level in India and, with vehicles in the states in short supply and poorly maintained, the provision of transport for the advisers was a problem. In Bihar, none was made available and, in general, state officials showed little interest and offered the minimum of cooperation in helping to solve difficulties of this kind. Not until 2 years later were the inadequacies of the Bihar health structure fully appreciated. Conceivably, more energetic measures in Bihar at that time might have averted the catastrophe that lay ahead.

Fig. 15.6. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1971.

Smallpox eradication activities continued in all states throughout 1971-1973, with varying levels of success. During this period there were developments of particular note in the western states and in Uttar Pradesh, as well as in certain of the areas of low incidence in the south, and an unanticipated setback originating in a Bangladeshi refugee camp in West Bengal. These are described below.

#### *Western India, 1971-1973*

It had been hoped that the dramatic success of the surveillance-containment programme in Gujarat might be repeated in the other western states and in Uttar Pradesh, in which epidemics were then beginning. Dr Monnier, assigned to Jaipur, the capital of Rajasthan, and Dr Moukhopad, assigned to Lucknow,

the capital of Uttar Pradesh, provided needed support. Full-time assignments were deemed advisable: in Rajasthan because health and other services were less well developed in this conglomerate of former princely states than in most of India; and in Uttar Pradesh because of its vast population (91 million) and its dismal performance during the mass vaccination campaign.

Rajasthan, besides having a less adequate structure of health services and a less literate population than much of India, was geographically a problem, nearly two-thirds of its area being desert and semi-desert. Roads were few and working conditions demanding. The population of 26.5 million was principally settled in 151 towns and 33 305 villages, but there were nomads as well. Three state teams were created which were directed, respectively, by the Deputy Director for Communicable Diseases, Dr M. L. Aggarwal; his deputy, Dr D. K. Jagdev; and Dr Monnier. Each was assigned a paramedical assistant. Vehicles were made available sporadically for the state officials but Dr Monnier used his private car for almost a year until it was agreed that WHO would provide him with a vehicle. In addition to training district and local staff in reporting and containment measures during their extensive travels and in specially convened meetings, the teams undertook to detect and contain outbreaks.

As in other countries, the discovery of suspected cases was usually accomplished by questioning village leaders, schoolteachers and their pupils, and people attending weekly

markets. In Rajasthan and in many other parts of India, there were two additional methods, unique to India, by which cases could be detected. One consisted in questioning visitors to the Sitalā mata temples. Many villagers came to give thanks to the goddess for recovery from smallpox or to offer homage in the hope that they and their families would be spared a visitation by the goddess. Cases could also be detected in villages when, as was customary in many areas, branches from the neem tree were hung over the front door of a house in which a patient lived. The leaves of the neem were considered to have special cooling properties when applied to the skin of the patient and other, less tangible, properties when hung above the doorway.

The programme in Rajasthan made commendable progress. At the beginning of the summer of 1971, the number of reported cases declined steeply, and the incidence remained comparatively low during the spring smallpox season of 1972 (Fig. 15.7). In October, in order to strengthen the programme, other health workers, such as the family planning and malaria eradication programme staff, were directed to report any smallpox cases found during the course of their work. A further decline in incidence occurred in 1973 (Table 15.13), and from August to October 1973 no cases whatsoever were detected. Cases occurred subsequently in Rajasthan, but they originated from importations. The results were impressive and what had been hoped for, although the programme was undoubtedly assisted, as in Gujarat, by a decline in incidence associated with the longer-term fluctuations of smallpox. Nevertheless, little more than 2 years had elapsed between the time the surveillance teams

had begun work and the unprecedented occurrence of 3 months without detectable smallpox.

Dr Singh, through such visits as he could make to the western states near New Delhi, was no less successful in stimulating effective surveillance–containment programmes. The number of cases in the contiguous states of Haryana, Himachal Pradesh and Punjab and in Delhi Municipal Corporation (total population, 32 million) fell somewhat less steeply than in Rajasthan, but by the winter of 1972–1973 fewer than 100 cases were being detected monthly, many of which resulted from importations from the neighbouring state of Uttar Pradesh. By September 1973, transmission had been interrupted throughout this entire area, the only reported cases resulting from importations into New Delhi.

Meanwhile, the programme in Gujarat had progressed so satisfactorily that only 44 outbreaks were detected during the first 6 months of 1971, and none whatsoever from July to the end of October. It seemed impossible that transmission could have been stopped in a state so heavily infected as recently as 1970. Accordingly, Arita was

asked to direct a special assessment of the state in November 1971. During a 3-week period, he led a 6-member team which visited 90 towns and villages in high-risk areas of 11 districts. No evidence of smallpox since June of that year could be found. The success reflected, in part, improved case detection and containment of outbreaks, but intensive vaccination undoubtedly also played a role. District surveys in September 1971 revealed that vaccination scars were present in 98–99% of those aged 5–14 years, in 96–99% of those aged 1–4 years and in 66–88% of those aged less than 1 year.

The smallpox eradication programme throughout the western states was progressing everywhere as had been hoped (Fig. 15.8) with a single exception—the northern state of Jammu and Kashmir (population, 4.8 million), which had once been free of smallpox. In the autumn of 1972, the state began reporting increasing numbers of cases. Until October, Jammu and Kashmir had experienced only occasional importations which, according to state reports, had been quickly contained. It had been hoped that by preventing smallpox from becoming re-established in Himachal Pradesh, a geo-

graphical barrier to the northward spread of the epidemic would be created, preventing the disease from reaching Jammu and Kashmir. Dr Singh, working with effective state programme staff, proved successful in maintaining the non-endemic status of Himachal Pradesh. Unfortunately, many travellers to Jammu and Kashmir imported smallpox from infected areas more than 50 kilometres away. Because of the paucity of senior smallpox advisers, assistance had not been provided to state staff in Jammu and Kashmir and the health services had been unable to cope. The failure to strengthen activities in this state was an omission for which the programme would subsequently pay dearly in additional effort.

#### *Uttar Pradesh, 1971-1973*

The development of surveillance-containment programmes in the western states proved to be comparatively straightforward, but in the adjacent state of Uttar Pradesh, the experience was entirely different. Uttar Pradesh was India's most populous state (population, 91 million) with a density of 300 persons per square kilometre. Most of the state comprises the Ganges river plain, where population densities were among the highest in India and where transport and communication services were quite well developed. There was an extensive, well-established infrastructure of health services and a large, reasonably well trained health staff. In retrospect, unexpected problems might perhaps have been foreseen because of Uttar Pradesh's poor performance in the mass vaccination campaign, and because it was the last state in India to replace the rotary lancet with the bifurcated needle (1971).

During 1971, Dr Moukhopad and the state programme officer travelled extensively to conduct regional training programmes for all district health officers and their programme staff. However, almost as soon as they were trained in reporting and in surveillance-containment procedures, they were transferred to other districts or assumed other duties. Many who reported substantial numbers of cases of smallpox from their districts were disciplined by the state Director of Health Services by being transferred to hardship posts on the grounds that the presence of cases was tacit evidence that they had not conducted an effective vaccination

campaign. Although other states followed this practice, none did so as frequently as Uttar Pradesh and neighbouring states in northern India. Continuing efforts were made by national staff and WHO advisers to persuade state officials that their actions were counter-productive, but with only partial success.

Progress in the programme in Uttar Pradesh was difficult to assess, in part because of the suppression of reports by district officers and in part because of the archaic state and national reporting system. During 1971, the number of cases reported from Uttar Pradesh to the Central Bureau for Health Intelligence never reached 500 per month, and indeed between July and September of that year fewer than 100 cases were notified each month for the entire state. The relevant data, reported to the Central Bureau and to WHO up to 26 October 1971, are shown in Table 15.14 (*Wkly epidem. Rec.*, 1971b). Even if one were to assume that there were 10 times as many cases as had been reported, not only Uttar Pradesh but India as a whole appeared to have very few chains of smallpox infection. On the basis of a growing experience with surveillance-containment programmes, it seemed reasonable to expect that transmission could be interrupted comparatively easily and rapidly. The greatest impediment in assessing the true situation and in deciding how best to deploy resources to achieve this goal was the reporting system.

In November 1971, the government and a new acting director of the Central Bureau for Health Intelligence agreed to modernize the reporting system so that its procedures would resemble those used in other countries. Each primary health centre was directed to notify to the district on Saturday of each week the total number of cases detected that week irrespective of the date of onset. If no cases were reported, a "nil" report was to be submitted. The submission of a nil report was a most important feature. Previously, the absence of a report had been assumed to mean an absence of cases when, in fact, the responsible medical officer may have been negligent in reporting or had decided not to report because there were a great many cases. Officials who had been accustomed to suppressing information through the simple expedient of not submitting a report found it difficult to indulge in deliberate falsification. The districts were asked to ensure that reports from all primary health centres were

<sup>a</sup> Data reported to WHO up to 26 October 1971 (*Wkly epid. Rec.*, 1971b). . . = data not recorded.<sup>b</sup> Population estimates by state are based on United Nations (1985) data for all of India proportionately allocated by state on the basis of the 1971 census.<sup>c</sup> No cases were reported during this period in the union territories of Andaman and Nicobar Islands, Dadra and Nagar Haveli, Lakshadweep, Pondicherry, and Mizoram, and the state of Meghalaya.<sup>d</sup> Became the state of Karnataka late in 1973.<sup>e</sup> Became the union territory of Arunachal Pradesh in 1972.

submitted and to compile all reports then available on the following Tuesday and to send them to the state smallpox eradication programme office. The state, in turn, was made responsible for ensuring that all districts reported and, on each Thursday, for telegraphing a report to the Central Bureau for Health Intelligence and the National Smallpox Eradication Programme office. Many months, and in some states several years, of work were required before the reporting system functioned well but a major obstacle to the achievement of eradication in India had at last been removed.

In November 1971, Uttar Pradesh was the first state to implement the new reporting scheme. By February 1972, the number of districts which had not reported for 3 weeks or more had fallen from 17 to only 5, and by summer, 48 of the 55 districts were submitting reports promptly each week. Whether because of improved reporting or

because of an actual increase in incidence, the number of recorded cases rose during the winter of 1971-1972 to between 1200 and 1600 each month (Fig. 15.9)—but still, in a population of 91 million, this was not a great number. Senior staff continued to believe that with sustained support to the surveillance-containment effort, Uttar Pradesh would repeat the experience of the western states. It was not to be. Smallpox eradication staff were diverted to perform cholera vaccinations between September and December 1972, at a time when the containment of smallpox outbreaks was most crucial. Although cholera vaccine had been shown to be of little value, this was the usual and politically acceptable response of the health services when cholera occurred. Explosive outbreaks of smallpox spread across the state; the number of cases increased rapidly during the early months of 1973, reaching a peak in May, when 5000 cases were reported.

Particularly discouraging was the continuing antipathy of state officials to the surveillance-containment strategy. An episode in early April 1973 in the district of Muzaffarnagar vividly illustrated the prevailing attitude. This district, located less than 100 kilometres north of New Delhi, began experiencing outbreaks of smallpox in the autumn of 1972 and, in January, reported 440 cases. This greatly exceeded the number reported that month by any other district of India except 2 districts in West Bengal associated with the Salt Lake Refugee Camp disaster (see later in this chapter). In February 1973, Arita joined Dr Moukhopad in a special investigation of the problem. Active searches at schools and markets soon revealed that although the reported smallpox incidence was high, there were many other undetected and uncontrolled outbreaks occurring throughout the district. With the cooperation of a responsible, energetic district health officer, they decided to mobilize all health staff throughout the district by closing the health centres and training the staff to undertake a 2-week systematic village-by-village search for cases. The health staff responded with enthusiasm and efficiency and soon discovered that cases were occurring in more than half the villages. In all, 641 cases were discovered in February and 1219 in March. Containment measures had scarcely begun, however, when the state Director of Health Services ordered

the cessation of all surveillance-containment operations and the immediate vaccination of the entire population of the district. He then warned that when this had been completed the report of any further cases would result in the transfer of the district health officer to the most unpleasant post in the state. It was clear that considerable persuasion of state officials and heroic efforts in the field would be required if Uttar Pradesh was to become free of smallpox. However, the demonstration that it was possible to mobilize effectively the poorly supervised army of health staff offered hope for the future.

#### *The southern states, 1971-1973*

In the southern states, it had been hoped that the WHO adviser, Dr Zikmund, working with state programme officers might succeed reasonably quickly in developing surveillance-containment activities to the point of interrupting transmission throughout the entire area. Tamil Nadu continued its successful programme and from the beginning of 1971 to the end of 1973 only 11 cases were recorded (Table 15.15), all following well-documented importations. Mysore (renamed Karnataka in 1973) and Andhra Pradesh, the contiguous states to the north, were targets of high priority. Virtually all cases in Andhra Pradesh occurred during the first half of 1971 among generally uncooperative, poorly vaccinated fishermen who migrated seasonally between Andhra Pradesh and Orissa. District health officials, considering them to be temporary residents, had ignored them. Once vaccination and outbreak containment began, transmission quickly stopped. In Mysore, 185 of the 223 cases reported during 1971 were from a single district and these outbreaks were contained by midsummer. Maharashtra was also successful in stopping transmission. In the entire southern area, between October 1971 and January 1972, only 45 cases were detected, all of them occurring in 3 districts. Considering that the southern states accounted for 38% of India's total population, there was reason for optimism about the prospects for the eradication of smallpox in India.

Uncertainty persisted, however, about the situation in the state of Kerala. There, smallpox transmission appeared to have been interrupted in 1967, only 42 cases, presumably importations, having been detected between 1968 and 1970. However, between January and May 1971, 105 cases were

Fig. 15.9. Uttar Pradesh State: number of reported cases of smallpox, by month, 1971-1973.

reported, with 1 additional case in September and 2 in November. Kerala's health services, among the best in India, reported that the cases had not occurred in outbreaks as one would expect, but rather were scattered across 7 of its 10 districts. Because the epidemiological pattern of the cases was difficult to explain, Arita joined state officials in a special study in February 1972. Of the reported cases, 70% were found to be in persons over 15 years of age, and of the patients whose vaccination status was known, 102 had previously been vaccinated. Arita and his collaborators examined 35 patients who had recovered, but none had the residual pockmarks typical of smallpox. As it turned out, the state in late 1970 had requested health staff to begin to collect specimens from patients with chickenpox as well as from those with suspected smallpox to confirm with greater certainty that the state was smallpox-free. A state laboratory with little experience in the identification of variola virus had examined the specimens using the gel-precipitation technique and reported that 104 out of 386 tested were either "positive" or "doubtful" for variola virus. Although there was little doubt on the part of physicians about the clinical diagnosis, the virological reports were accepted and the cases duly notified. The team eventually concluded that none of the reported cases was smallpox and the reports were retracted. Except for 4 imported cases in 1974, Kerala was to remain smallpox-free.

The findings in Kerala provided further encouragement but, in February 1972, it

suddenly became apparent that there were serious, hitherto unrecognized, problems in Mysore. The discovery of smallpox in Mysore was made by surveillance teams in the neighbouring state of Andhra Pradesh, whose programme was directed by Dr M. C. Appa Rao. There, case detection had improved significantly when, at the end of 1971, a sum of 10 rupees (US\$1.33) was awarded by the government for the discovery of a case—the first time in India that such a reward had been offered. The teams detected outbreaks in Hyderabad whose source of infection was a village in Gulbarga District, one of 19 districts of Mysore State. The outbreak was unknown to the Mysore state programme officer. The district (population, 1.7 million) had an extensive network of health facilities, including a large general hospital, 71 health centres and dispensaries, a medical college, and special programmes for the control of malaria, filariasis and tuberculosis and for family planning. It was assumed that if smallpox cases had been present, they would have been quickly detected. State officials, in collaboration with Dr Zikmund, began an immediate investigation. It soon became apparent that not one but numerous outbreaks had occurred, beginning almost 15 months earlier, in December 1970. By the end of March, the investigators had discovered 81 outbreaks and 730 cases. They found that even the staff members of primary health centres who lived in villages with major outbreaks had not reported them; many directors of primary health centres who were notified of cases dismissed them as chickenpox; and, indeed, the District Director of Health and Family Planning, who had been officially informed of smallpox cases as early as September 1971, had suppressed the reports. It was concluded that radical measures would be required to stop the epidemic.

Able leadership was provided by a newly appointed District Medical Officer of Health, Dr Rama Rao; health staff were transferred from other districts; and all health and family planning staff in Gulbarga District were mobilized to undertake repeated house-to-house searches for cases throughout the district. When outbreaks were discovered, they were promptly contained. New outbreaks rapidly decreased in number, from 34 in April to 12 in May and 4 in June. To counter the tendency to conceal cases, a reward of 25 rupees (US\$3.33) was offered to anyone who reported a case of smallpox.

Table 15.15. Southern India: number of reported cases of smallpox, 1971–1973<sup>a</sup>

State or union territory	1971	1972	1973
Andhra Pradesh	214	405	1 295
Dadra and Nagar Haveli	0	0	1
Kerala	0	0	0
Maharashtra	160	215	158
Mysore <sup>b</sup>	223	1 299	6
Orissa	16	5	1 276
Tamil Nadu	7	1	3
Total	620	1 925	2 739
Other states and union territories of India	15 570	25 482	85 375
Grand total	16 190	27 407	88 114

<sup>a</sup> No cases were reported during this period from the union territories of the Andaman and Nicobar Islands, Goa, Daman and Diu, Lakshadweep, and Pondicherry.

<sup>b</sup> Became the state of Karnataka late in 1973.

### Chickenpox—a Problem in Surveillance in Kerala

Cases of and deaths from severe chickenpox proved the most difficult in differential diagnosis. The most problematic cases were those in adults. Among residents of the southern state of Kerala (population, 24 million), as well as among migrants from that state, cases of chickenpox in adults occurred with unusual frequency, and this resulted in a number of erroneous reports and special investigations. In the process of confirming that transmission had been interrupted in India, a special study was conducted in Kerala to ascertain that the deaths attributed to chickenpox had been correctly diagnosed (White, 1978).

#### *Age Distribution of Deaths Due to Chickenpox, January 1975–March 1976*

<i>Age group (years)</i>	<i>Males</i>	<i>Females</i>	<i>Total</i>	<i>Prevalence per 100 000 of cases of chickenpox<sup>a</sup></i>
0–4	6	3	9	64
5–9	2	1	3	102
10–19	4	3	7	87
20–29	1	3	4	59
30–39	14	3	17	56
40–49	34	1	35	69
50–59	34	5	39	48
60–69	31	14	45	31
≥70	74	27	101	36
Total	200	60	260	71

<sup>a</sup> Based on a special search in April 1976 in 11 primary health centres.

Of 260 persons who died of chickenpox over a 15-month period, 241 were 20 years of age and older. For many, the immediate cause of death was attributed to "old age" or a chronic or unrelated acute illness, although chickenpox may have been cited as a contributory factor.

It was suggested that the frequency of adult cases related to the dispersed population in Kerala and, until recently, the difficulty of travelling from one village to another. Thus, it was reasoned, many were not exposed to chickenpox until they were adults. The hypothesis was attractive, but other factors must have been involved because adult chickenpox was not such a problem in other, even more isolated, areas of Africa and Asia.

However, cases spread from Gulbarga to 5 other districts in Mysore, to 2 districts in Andhra Pradesh and to at least 1 district in Maharashtra. More than 1400 cases in all were traced to this single district. Although the outbreaks were largely contained in a period of 2 months, fully 6 months elapsed before transmission finally ceased. Most surprising to senior Indian and WHO staff alike were the numbers of health staff who could be mobilized, the rapidity with which a search programme could be organized, and the responsiveness of staff in executing a well-conceived plan. This experience was subsequently replicated in Muzaffarnagar District, Uttar Pradesh (see previous section) and, in May 1973, throughout Orissa State. It

ultimately led to the plan to undertake nation-wide searches for smallpox cases—the essential strategic component of the campaign beginning in the autumn of 1973.

Although transmission was successfully interrupted in Mysore by September 1972, Hyderabad, the capital of Andhra Pradesh, had by then been reinfected; from there the disease spread to 8 other districts. Dr Appa Rao, who was responsible for other programmes in addition to smallpox eradication, was unable to devote sufficient time to the programme and smallpox continued to spread, albeit slowly. Smallpox was reasonably well contained, with the help of Dr Zikmund, until January 1973, when he was forced to leave for Orissa because of outbreaks there

resulting from importations from the Salt Lake Refugee Camp. Smallpox continued to spread in Andhra Pradesh. Between January and June 1973, 924 cases occurred. In view of the size of the population (47 million), the number of cases was not large but, clearly, transmission in Andhra Pradesh and the southern states was not being interrupted as quickly or as easily as had been hoped. The potential for epidemic spread remained, as the Gulbarga experience had shown. The movement of smallpox was too rapid and effective to be contained by the few epidemiologists available.

*West Bengal and the Salt Lake Refugee Camp, 1971*

The densely populated state of West Bengal (population, 46 million), with its crowded capital city of Calcutta (population, 7 million), was a demographic centre of vital importance to smallpox eradication in the eastern states of India. In West Bengal, progress in the control of smallpox appeared to be satisfactory—until December 1971. The number of recorded cases had diminished to only 374 in 1970 and to 217 in 1971, the lowest totals ever reported. The Eastern Province of Pakistan (later Bangladesh) on its eastern border, predominantly Muslim but also Bengali-speaking, had detected its last case in August 1970 (see Chapter 16). Thus, importations of smallpox by travellers who frequently crossed the border were not a threat. However, civil war began in March 1971 in East Pakistan, and during that year an estimated 10 million refugees fled across the border into India. Numerous refugee camps were set up, primarily in West Bengal, Madhya Pradesh and Assam. It was feared that if smallpox were introduced into the camps, devastating epidemics would rapidly develop. On the orders of the National Smallpox Eradication Programme staff, all refugees entering the camps were examined for the presence of smallpox, but no cases were found. As a preventive measure, state officials were requested to ensure that all persons entering the camps were vaccinated. Indian national staff and WHO advisers visited and confirmed that this procedure had been followed in a number of camps, but not in West Bengal, where the state authorities refused to permit national intervention. The largest refugee camp, the Salt Lake Camp near Calcutta, sheltered an estimated 200 000–300 000

persons, and there an international private voluntary organization had been given responsibility for providing health services. For reasons unknown, no vaccination campaign was conducted.

Smallpox was probably introduced into the Salt Lake Camp in November. Many cases were hospitalized within the camp but were diagnosed as chickenpox. The diagnosis of probable smallpox was finally made on 19 January 1972 by an epidemiologist in the USA while viewing a television news documentary made in the camp. The report was relayed rapidly from Atlanta to Geneva to New Delhi. The Director of Health Services of West Bengal categorically denied there were cases, but Dr S. N. Ray, from the National Programme office, flew to Calcutta and, on visiting the camp, found an extensive outbreak. A vaccination programme was begun, but it was too late. On 16 December 1971, one month earlier, the independence of Bangladesh had been proclaimed. By 20 January 1972, an estimated 50 000 refugees had already departed for Bangladesh. The epidemic spread from the camp through West Bengal and from there to the neighbouring states of Orissa and Bihar. West Bengal, which had detected only 217 cases in 1971, reported 4753 in 1972; Bihar reported 1307 cases in 1971 and 4153 in 1972.

The number of cases that occurred in the camp can never be known, but as from 22 January, infected persons among the refugees remaining in the camp were admitted to the Calcutta Infectious Diseases Hospital; admissions continued until the end of February. During this period, the hospital admitted 764 patients, of whom 48% died (Guha Mazumder & Chakraborty, 1973).

West Bengal, which had been comparatively free of smallpox in 1971, became a major epidemic focus in 1972 (Fig. 15.10) and Bangladesh was again reinfected (see Chapter 16).

*The beginning of the "final phase" of the Intensified Smallpox Eradication Programme, November 1972*

By the autumn of 1972, global progress in the Intensified Programme was most encouraging. Only 3 endemic countries remained in the whole of Africa—Ethiopia, Botswana and the Sudan—and in the latter two interruption of transmission appeared imminent. Both South America and Indonesia were smallpox-

free and Afghanistan was almost so. Bangladesh had been reinfected but it had re-established its national programme and Pakistan's programme had been extended to the entire country. India was reporting increasing numbers of cases as epidemic smallpox began moving across the Ganges plain from the west and from Calcutta in the east. However, the extent of the infected areas in India, as well as in other Asian countries, had diminished significantly (Fig. 15.11).

With endemic smallpox so limited geographically and some form of surveillance operating in all areas, it seemed to WHO propitious to encourage a more concentrated effort in the remaining infected areas: the "final phase" of the Intensified Programme. The proposed target was ambitious—to interrupt smallpox transmission during the following 2 smallpox seasons, a period of about 18 months. To encourage the renewed effort, special seminars were convened in

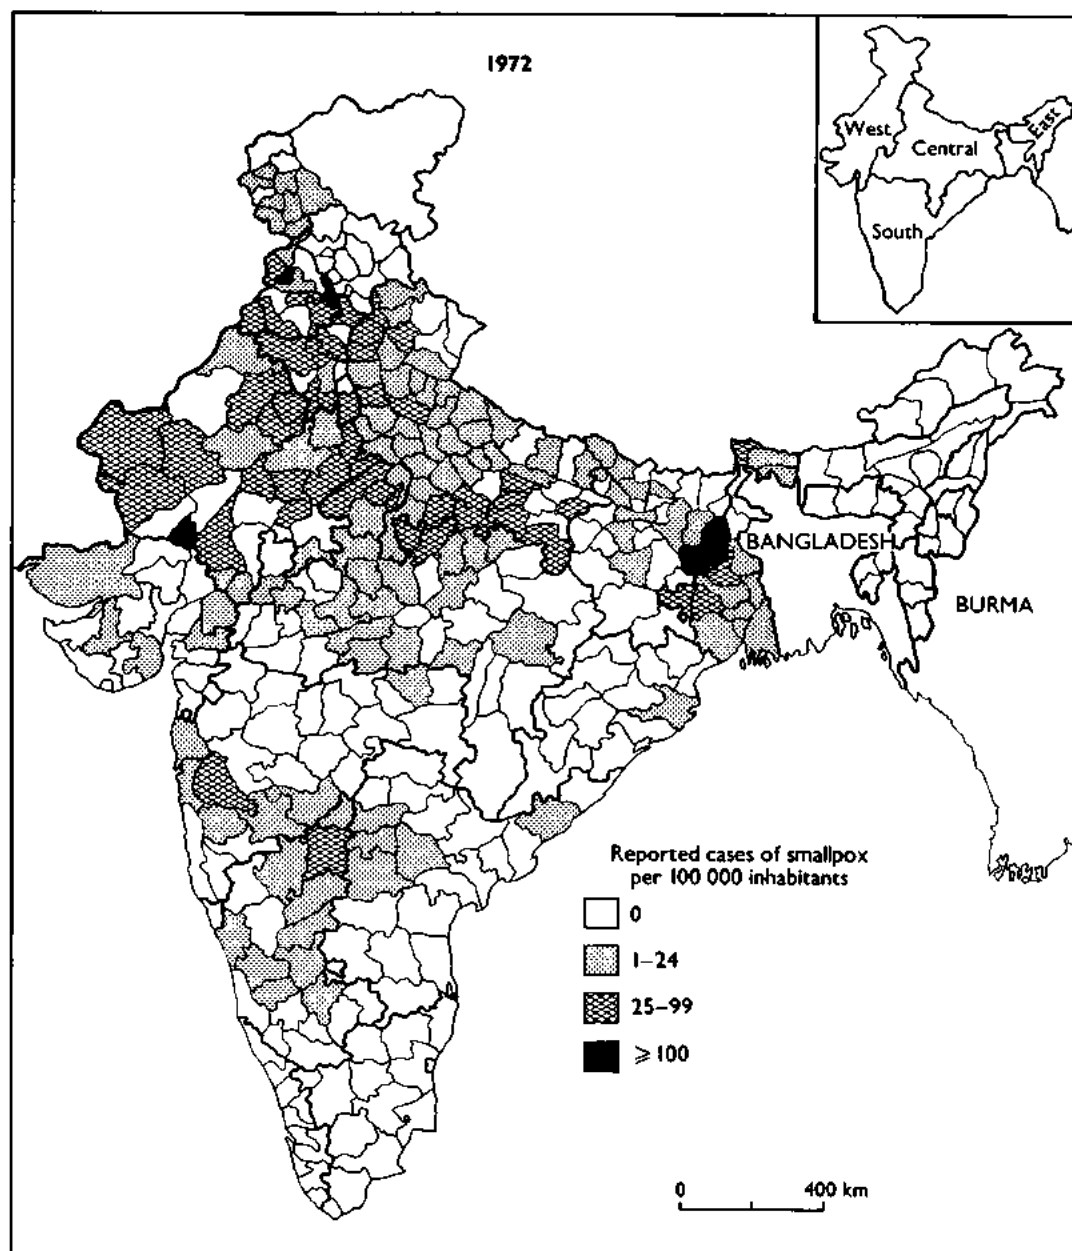

Fig. 15.10. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1972.

September–November in Addis Abeba (mainly for staff in Ethiopia and the Sudan); in Karachi (principally for staff in Afghanistan and Pakistan); and in New Delhi (for staff in Bangladesh, Bhutan, India and Nepal).

In India, despite the success of surveillance–containment measures in southern and western states, many state health officials still persisted in their belief that 100% vaccination was the only way to achieve eradication. With officials from all over India attending the seminar, attention was focused explicitly on the surveillance–containment strategy. The success in Indonesia was a helpful stimulus in encouraging a change in direction, as is illustrated in the following extract from Henderson's opening address:

"Two years ago, in December 1970, a seminar on smallpox eradication was held in this very room. I said at that time that the question was repeatedly asked as to how such major changes [in the smallpox eradication programme] could occur so rapidly when, for years, many endemic countries had been conducting mass vaccination programmes with only limited success. The principal difference between present and past efforts is one component—surveillance. In every country where a concerted effort has been made to investigate promptly and to contain *every* outbreak, smallpox transmission has been interrupted within two years or less. Many of you will recall that at that Seminar the director of the Indonesian programme presented a provocative paper which stated 'a proper surveillance–containment action brought smallpox under control in a short period,

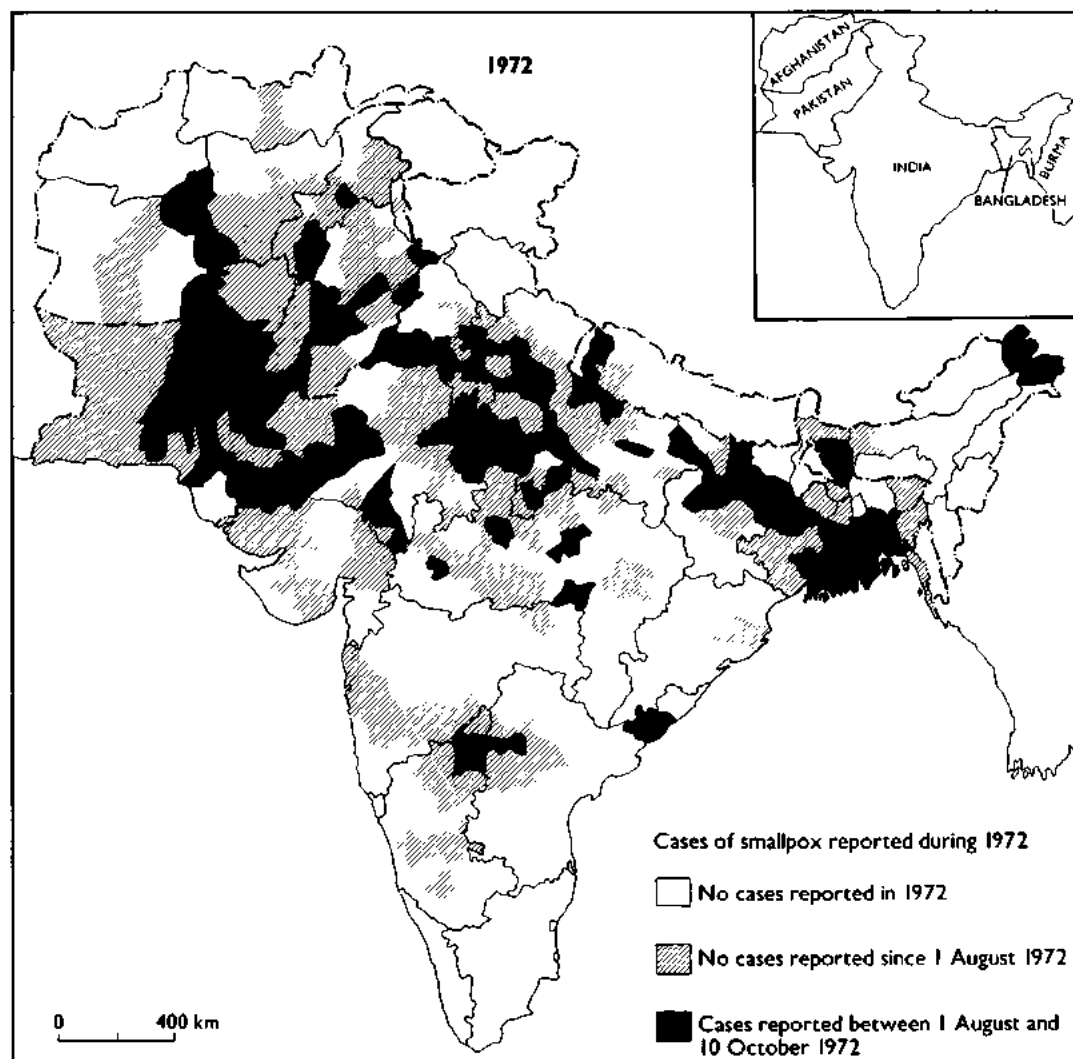

Fig. 15.11. Indian subcontinent and adjacent countries: areas reporting cases of smallpox during 1972 (as of 10 October).

while on the contrary, routine vaccination and mass vaccination campaigns had little effect in interrupting smallpox transmission'. That year, Indonesia reported 10 000 cases of smallpox, only 20% fewer cases than in India. Many at that Seminar took violent exception to the Indonesian director's contention that all available resources should be diverted to surveillance even at the expense of a vaccination campaign. Who was

right? I would ask you to note that the number of cases in Indonesia decreased from 10 000 in 1970 to 2000 in 1971 and to 34 this year. Despite a continuing active search for cases, none have been found in all of Indonesia for over eight months."

State health authorities in India had argued that there were not enough health staff. However, it was noted that, even in countries

**Plate 15.5.** Refugees from East Pakistan, many infected with smallpox, leave the Salt Lake Camp near Calcutta in December 1971 to return to their newly independent country, Bangladesh.

with less well developed health infrastructures, such as Ethiopia, only 80 workers were employed (1 for every 300 000 persons) and in Afghanistan the corresponding ratio was 1 for every 100 000 persons. In India, 1 smallpox vaccinator was available for every 8000–20 000 persons.

The need for surveillance was echoed in the address by the Indian Minister for Health and Family Planning and by Dr P. Diesh, the Additional Director-General of Health Services, who concluded the seminar with the statement: "History tells us that whoever rules the Indo-Gangetic plain rules the country. The battle of smallpox will be fought in the Indo-Gangetic plain, where 70% of the cases are reported now." And this indeed was where the major battle was fought over the following 3 years.

The seminar report concluded with a number of recommendations which stressed surveillance:

1. It is essential to delineate smallpox endemic and non-endemic areas within a state or country. The endemic areas should receive highest priority and the major part of the resources at present available. In the non-endemic areas, an active search for cases should be planned and implemented to ensure their smallpox-free status. Any suspected cases should be dealt with as a national public health emergency.

2. In states where surveillance teams are not yet in existence, state teams should be created by 1 December 1972.

3. The investigation of all outbreaks by the state programme officer or at least by state surveillance teams is essential.

Other recommendations emphasized the importance of containment and the need to trace the source of outbreaks. It was also noted that "the newly introduced reporting system in India should be improved as rapidly as possible". The new system was that previously described, in which primary health centres, districts and states reported weekly all cases of smallpox detected during a given week or reported "nil" if no cases were found.

The central programme office was further strengthened in the autumn of 1972, with the appointment of a senior public health officer to head the programme, Dr R. N. Basu, Assistant Director-General of Health Services (Smallpox), who continued in this position until the conclusion of operations. Dr Basu, who held a more senior rank than Dr Singh, carried greater weight with national and state officials. Dr Diesh, who was effec-

tively second in command to the Director-General of Health Services in the Ministry, also took a special interest in the programme and made a number of visits to the state capitals to meet health ministers and directors of health services in order to encourage greater activity. Visits by an official of this rank were uncommon and implicitly indicated that the government accorded high priority to the smallpox eradication programme. Meanwhile, working relationships between WHO staff and Indian national and state staff had gradually become less formal. Arrangements for WHO staff from the regional office to travel to the field and for state-assigned staff to travel from state to state had become a simple matter of discussion and verbal agreement. This was in marked contrast to the earlier formal relationships which required that, before each trip, a written request should be submitted by the WHO Regional Director to the Ministry of Health and that this request should be considered within the Ministry and eventually a formal reply prepared—a process that often took weeks. With each adviser in possession of a vehicle purchased by WHO and an agreement by WHO to defray all travel costs, a further obstacle to the execution of the programme was removed.

**Plate 15.6.** Rabinder Nath Basu (b. 1928), Assistant Director-General of Health Services, was appointed to direct the National Smallpox Eradication Programme in the autumn of 1972 and continued in this capacity until after the certification of eradication in 1977. He subsequently directed the development of India's Expanded Programme on Immunization and later became the Director of the National Institute of Communicable Diseases.

7 JEFK

**Plate 15.7.** Outbreaks of smallpox occurred among poorly vaccinated pavement dwellers in crowded urban areas. The discovery and containment of such outbreaks were a continuing problem throughout the course of the Intensified Programme.

At the November seminar, goals were fixed in terms of geographical areas within which it was hoped endemic smallpox could be contained by the end of March 1973. For India, it was agreed that by that date the objective would be to eliminate endemic smallpox from all areas except the state of Bihar and 49 districts comprising parts of Uttar Pradesh, Madhya Pradesh and West Bengal.

As early as the end of December 1972, it was evident that the problems once again were greater than had been anticipated. As has been mentioned earlier, major epidemics were discovered in the previously smallpox-free state of Jammu and Kashmir. In Bihar State, health workers went on strike, bringing all work to a standstill. In Uttar Pradesh, then the principal focus of smallpox, eradication staff had been diverted to a cholera vaccination campaign. The new reporting system was an improvement over the old one but, even so, half or more of the states and union territories were consistently up to 5 weeks late in reporting cases.

During 1972, 27 407 cases of smallpox were reported from India, an increase of 69% over the 16 190 cases reported the year before. More complete notification undoubtedly ac-

counted for some of the increase but there was no way of measuring the magnitude. In January 1973, predictions as to the expected incidence of smallpox in 1973 were made by WHO Headquarters staff, in consultation with national staff, on the premise that such predictions served to gauge familiarity with the problems in each area, the rate of progress being made or anticipated and the understanding of the epidemiological situation. It was forecast that 30 700 cases would occur throughout the world, of which 17 000 would be in India. It soon became evident that neither WHO nor Indian staff had comprehended the magnitude of India's smallpox problem.

By the end of March 1973, India had recorded 14 376 cases, of which 29% were outside the established target area. Not only were serious problems present in Bihar, Uttar Pradesh, and Jammu and Kashmir, but it had also become apparent that West Bengal had not done well in controlling the epidemic which had spread from the Salt Lake Camp area. By the end of February, 19 cases imported from Calcutta were detected in Orissa and 30 in Bihar. The estimate of the total number of cases in India projected for 1973 was revised upwards from 17 000 to 35 000

and then to 60 000, a figure which would represent the highest number of cases since 1967. Although reporting had undoubtedly improved, smallpox was far more extensive than had been expected; many still did not subscribe to the new strategy of surveillance and containment. During the spring of 1973, smallpox incidence continued to rise and by the end of June, 49 478 cases had been reported, of which 45 697 (92%) were from the 4 contiguous states in or immediately adjacent to the Gangetic plain—Bihar, Madhya Pradesh, Uttar Pradesh and West Bengal. The total number of cases was almost 3 times greater than the number recorded during the same period in 1972. Comparisons with trends in Pakistan and Bangladesh (*Wkly epidem. rec.*, 1973b) portrayed the unfavourable situation in India (Fig. 15.12).

India was then one of only 4 countries in the world with endemic smallpox, and it accounted for nearly 60% of the world's cases. Politicians and senior health officials alike had become increasingly concerned and had taken a greater interest in the programme. The Twenty-sixth World Health Assembly in May 1973 provided an added stimulus.

During discussions in the Health Assembly regarding the smallpox eradication programme, the delegate from Malaysia bluntly assessed the situation. His observations were summarized as follows (World Health Organization, 1973b):

"... an alarming development in recent months had been that serious smallpox epidemics were raging in two of the endemic countries, despite the fact that WHO was now entering the seventh year of its intensified smallpox eradication programme. Among the reasons for the setback, as given in the *Weekly Epidemiological Record* ... were: lack of staff; inadequately developed surveillance programmes; periodic diversion of smallpox staff to other programmes; delayed and incomplete reporting; and inadequate containment measures. Lack of staff should not be an insurmountable problem; it could be overcome by improved deployment of staff and crash recruitment and training programmes. Nor should it be too difficult to organize and develop surveillance programmes. In view of the vital importance of smallpox eradication, any diverting of staff to other programmes would be premature and ill-advised, and inadequate reporting and containment measures indicated a lack of appreciation of the urgency of the problem. He did not wish to criticize any individual country, but he hoped that the points he had raised would be taken in a constructive spirit.

Fig. 15.12. Bangladesh, India and Pakistan: number of reported cases of smallpox, by month, 1971-1973 (as of 19 June 1973).

"WHO had declared that it was willing to send emergency aid on request ... to any country facing problems in smallpox eradication. He wondered whether the countries now suffering from outbreaks had taken full advantage of that offer ..."

In the World Health Assembly, criticism such as this of another country's health programme was unusual; to India's Director-General of Health Services, it was acutely embarrassing. He returned to India determined to strengthen the programme.

Endemic smallpox in India remained comparatively limited geographically (Fig. 15.13) although the number of cases was large, and it appeared that an intensified programme would require a special mobilization of resources in only a few states of India. With the season of diminished transmission immediately ahead, it was decided to initiate an "epidemic of activity" preceding the usual season of epidemic smallpox.

#### The Intensified Programme in India, June-December 1973

At the end of June 1973, WHO staff from Headquarters and the Regional Office for South-East Asia held meetings with Indian national and state health personnel to devise a new campaign plan whose strategy would be to detect and contain the comparatively

Fig. 15.13. Indian subcontinent and adjacent countries: areas reporting cases of smallpox during 1973 (as of 19 June).

few outbreaks expected to occur during the autumn months of seasonally low incidence. If most of these could be contained by December, it was expected that the remaining foci could also be contained by state and district surveillance teams during the January-June period.

The most highly infected states were Bihar, Uttar Pradesh and West Bengal. There, the deployment of an epidemiologist-adviser and a few surveillance teams for motivating local staff to report cases and to contain outbreaks had clearly failed. A different approach was required. The early detection of cases was of the greatest importance. Once cases were found, a comparatively small number of

containment teams could deal with the outbreaks. Everyone had been impressed by the experiences in Gulbarga District (Mysore) and Muzaffarnagar District (Uttar Pradesh), in which it had proved quite simple to plan and execute a village-by-village programme of case detection which could reach all parts of a district within 1-2 weeks. It was reasoned that if a systematic search of this type could be conducted throughout entire states, in combination with an effective containment programme, it should be possible to contain smallpox quickly. To execute such a search in a state, in a group of states or in the whole of India posed problems of organization and motivation of an entirely

different magnitude from those involved in carrying out the operation in a single district. However, it was apparent that throughout the length and breadth of India a large complement of generally well-trained health staff existed—albeit often poorly supervised and supported. It seemed plausible that an increased number of senior smallpox eradication programme supervisors, following a carefully designed plan, could harness this considerable resource for a concerted effort over a period of a few months. This was the basic strategy decided on, and thus began what was to become one of the most ambitious and intensive national health programmes yet undertaken. Eventually, it would involve more than 130 000 staff who, within a 2-week period, could visit more than 90% of the 120 million households in India.

The principal problem area comprised the states of Bihar, Madhya Pradesh, Uttar Pradesh and West Bengal. Their combined population amounted to 249 million, or about 42% of the entire population of India. It was planned to assign a senior Indian epidemiologist and a counterpart WHO epidemiologist-adviser to assist each state smallpox eradication programme officer in these 4 states. An additional WHO epidemiologist would continue to work in the

neighbouring state of Rajasthan, in which transmission appeared to have been interrupted but which was experiencing many importations. A sixth WHO epidemiologist would be based in Orissa State to assist in the development of search programmes and the investigation of outbreaks in the low-incidence states and union territories geographically close to the 4 highly infected states. He would also assist with any problems in a third group of states which were thought to have interrupted transmission or were expected to do so by September—the smallpox-free group (Fig. 15.14). Additional transport, supplies and equipment were made available by WHO to supplement the already considerable resources deployed by India.

For the 4 highly endemic states, a 3-phase programme was formulated. Phase One, planned for the late summer of 1973, would consist of an active search for outbreaks in municipal areas. It was hoped by this search to find and eliminate urban foci, which often served to sustain smallpox transmission through the summer monsoon season. Because there was insufficient time for preparation, the first phase achieved little except to bring the smallpox eradication activities of most of the autonomous municipal corporations under the supervision of the state smallpox eradication programme office. Phase Two of the programme, from September to December 1973, would consist of state-wide, week-long, village-by-village searches on 3 separate occasions approximately a month apart. Two searches would be conducted in the states with a low incidence, and at least 1 search in the states believed to be smallpox-free. Other health personnel and family-planning workers would be utilized to supplement the work of the smallpox eradication staff. The nature of Phase Three, commencing in January 1974, would depend on the status of smallpox at that time; it was expected that it would consist primarily of a search for cases by surveillance teams and the containment of a few remaining outbreaks.

The government of India and WHO agreed to increase the number of senior supervisory staff for this effort. The government provided an additional senior Indian epidemiologist for each of the 4 priority states. It assigned to the programme Dr M. I. D. Sharma, then the Director of the National Institute of Communicable Diseases; two of his epidemiologists, Dr C. K. Rao and Dr R. R. Arora; and the Assistant

BY COURTESY OF R. S. AGARWALA

**Plate 15.8.** State review meeting in Lucknow, Uttar Pradesh, in 1975. Seated, left to right: M. C. Chaturvedi, Additional Director of Medical and Health Services of Uttar Pradesh; C. K. Rao, member of the Central Appraisal Team; J. M. McGinnis, WHO consultant from the USA; M. I. D. Sharma, Commissioner of Rural Health for India; and N. C. Grasset, smallpox adviser from the WHO Regional Office for South-East Asia. Standing: M. Dutta, member of the Central Appraisal Team.

Director-General for Cholera, Dr Mahendra Dutta. With Dr Basu and Dr Singh of the National Smallpox Eradication Programme, and Dr S. N. Ray, who was responsible for vaccine production, they constituted the Indian component of a group officially termed the "Central Appraisal Team". The WHO component consisted of the intercountry team (formally, the Smallpox Eradication and Epidemiological Advisory Team), Dr Grasset and Ježek, who were joined that summer by Dr William Foege, who had formerly worked in Nigeria and then at the Communicable Disease Center (later called the Centers for Disease Control) in Atlanta, GA, USA, in directing the smallpox eradication effort in western Africa. In January 1974, Dr Lawrence Brilliant, a new member of the WHO smallpox eradication programme staff, became part of the team.

Beginning in June 1973, the group held frequent meetings, preparing, reviewing, and revising drafts of a "Model Operational Guide for Endemic States" and a "Model Operational Guide for Non-endemic States". To implement the programme in the field, 26 special teams were created. Half the teams were headed by Indian epidemiologists recruited by the government from Indian institutes and universities or brought back from retirement. The other half were headed by epidemiologists of other nationalities recruited by WHO. Twenty-two teams were assigned to the high-incidence states (10 to Uttar Pradesh, 2 to West Bengal, 5 to Bihar and 5 to Madhya Pradesh); 2 teams worked in the eastern states; and the remaining 2 in the smallpox-free and low-incidence states in the south.

Eventually, a total of 230 epidemiologists from 31 countries and a comparable number

of Indian epidemiologists would head such teams for periods of 3–24 months each. As many as 90 epidemiologists would be participating at any one time. Each epidemiologist was given 5 days' training before going to the field. Particularly useful for this purpose was a series of slides prepared by WHO illustrating clinical smallpox and 2 case-history studies, one of which dealt with the day-by-day management and investigation of a smallpox outbreak and the other with the management of a district smallpox eradication programme. (The latter eventually found its way into the syllabus of the Harvard School of Business Administration.)

As the autumn campaign began, there were only 26 epidemiologists in the field (Table 15.16). Each epidemiologist in the high-incidence states worked in a zone covering an average of 5–6 districts (approximately 10 million people) and had as his counterpart the division and/or district health officer responsible for the area. The special teams conducted training sessions for district and local staff to explain and organize the searches. In addition, they supervised the implementation and evaluation of surveillance activities and verified the diagnosis when cases were reported. When smallpox was detected, they organized outbreak containment and identified the source of infection.

Additional vehicles were essential and these were quickly obtained through the purchase by WHO of Jeeps manufactured in India. For WHO, this was a departure from a long-standing policy that the country itself should purchase locally produced equipment and supplies. Prompt delivery of the vehicles would have been impossible if traditional procedures had been followed—i.e., the purchase of Indian-made Jeeps by the government or the purchase of foreign-made vehicles by WHO. To have manoeuvred

such a purchase through the complex Indian bureaucracy, even with the highest level of government support, would have taken anything up to a year; the delivery of vehicles from foreign sources was even more protracted at that time. The Indian-made Jeeps, although more susceptible to mechanical failure, were simpler in design and easier to repair. A most important consideration was that spare parts were widely available and there were many mechanics who were familiar with the vehicle. On balance, the Indian Jeeps proved more utilitarian than did imported vehicles.

Each of the epidemiologists was assigned a driver and a paramedical assistant and given a monetary advance (an imprest account) to be used, as necessary, for petrol and vehicle repair, travel allowances and supplies. The funds were accounted for at regular intervals before further advances were made. The disbursement of funds for the discretionary use of the field epidemiologists was also a departure from customary administrative practice, but it was one of the most important steps in facilitating the execution of the programme.

The strategy of the search programme and of the surveillance-containment activities was explained in detail at state-level meetings presided over by state officials and attended by senior officials of the national government and WHO, as well as by state and divisional and/or district health officers. These discussions were followed by similar meetings at the divisional level (for states with a divisional structure) convened by the commissioners of the divisions and attended by chief medical officers of health from the districts and municipal corporations. Meetings were then held at the district level, attended by the district health officers and primary health centre medical officers. Lastly, searchers and

supervisors at each primary health centre were instructed in the specific techniques of search, outbreak containment and reporting. Such meetings at different administrative levels were subsequently conducted before each new search; the experiences of the previous search were evaluated and additional or revised procedures implemented.

To organize the numerous meetings and to develop strategy over the extensive area involved required an extraordinarily intensive effort on the part of the Central Appraisal Team. As an illustration of this endeavour, one may cite the experience of a member of the team who travelled more than 1800 kilometres by car in 5 days, during which he participated in 7 district and regional meetings. To do so necessitated driving all day and through the night; the team member and his driver shared this task, alternately driving and sleeping in the cramped Jeep.

The organizational plan called for one search worker to visit one village or section of a city each day. The hundred or more villages in each primary health centre area were divided up among the staff of 15–20 health

workers. To facilitate supervision, a search schedule determined which worker would be in which village on which date. Each search was planned to be completed within 7–10 days. A supervisor oversaw the work of 4 or 5 workers and was assigned villages to be checked at random.

The searchers were instructed to show the WHO smallpox recognition card (see Chapter 10, Plate 10.11) and to inquire about any suspected cases that had occurred during the preceding 2 months. All village leaders and watchmen were to be contacted, as well as schoolteachers and their pupils, and persons congregating in tea-shops and market areas. Two or 3 houses in each of 4 parts of a village and the section of a village or town in which the poorest families lived were also to be visited. When the teams travelled from village to village, they were instructed to stop at brick kilns, bus stands, migrant camps and festivals to solicit reports of possible cases of smallpox.

Suspected cases were to be notified immediately to the primary health centre physicians, who were asked to verify the diag-

nosis. In addition to the assessment of work by the supervisors, each primary health centre medical officer was expected independently to assess one village or urban area assigned to each supervisor; each district-level supervisor was expected to visit one village, one school and one market in each primary health centre area; and each state surveillance team was expected to check 100 villages, 10 markets and 30 schools after each search. Areas selected for assessment were the least accessible villages and those most distant from the primary health centre. It was assumed that if the work was well done in the more distant and difficult areas, it was likely to be satisfactory in the areas easy of access. Radio, press, and other media were utilized to inform the public where to report cases of smallpox.

The first searches in the highly endemic states began in September. With such large populations and with so many health staff involved, the logistic requirements were formidable, as will be appreciated from the following inventory of material supplied to West Bengal for its first search: 100 copies of the Operational Guide; 10 000 smallpox recognition cards and 3000 large recognition cards; 100 copies of each district map to be used to plan search workers' schedules; 3000 copies of the searchers' village-by-village schedules; 16 000 copies of forms for recording the results of the village

visit; 400 copies of forms for listing outbreaks; and 3000 copies of the weekly reporting form to be dispatched from the primary health centres to the district. For a country-wide search, it was calculated that 8 tonnes of forms would be necessary.

Because of floods, only 9 out of 16 districts in West Bengal could be reached during the September search; but only 75 cases of smallpox were detected. It was uncertain whether the search had been good and the few cases that existed had been found, or whether it had been poor and many cases had been missed. However, a more extensive search conducted throughout the state in early October identified only 143 infected villages among West Bengal's 38 000 villages and 137 towns. Moreover, Calcutta, which many had feared might harbour extensive foci, had far fewer cases than had been expected.

The encouraging reports from West Bengal were quickly followed by alarming—almost unbelievable—reports from Uttar Pradesh and Bihar. During the week preceding the search, only 354 cases in 21 districts had been reported in Uttar Pradesh and only 134 cases in 8 districts in Bihar. However, the 1-week October search revealed 1525 outbreaks with 5989 cases in Uttar Pradesh and 614 outbreaks with 3826 cases in Bihar (Fig. 15.15; Table 15.17). It should be noted, however, that outbreaks occurred in only

Table 15.17. Bihar, Uttar Pradesh and Madhya Pradesh: results of the 1973 search for outbreaks of smallpox

State	Month of search	Number of towns and villages	Number of villages with new outbreaks (% of total)	Number of municipalities with new outbreaks	Total number of new outbreaks found	Number of new cases found
Bihar	Oct.	67 727	601 (0.9)	13	614	3 826
	Nov.		484 (0.7)	21	505	2 459
	Dec.		385 (0.6)	20	405	2 619
Uttar Pradesh	Oct.	112 854	1 483 (1.3)	42	1 525	5 989
	Nov.		390 (0.3)	24	414	1 711
	Dec.		309 (0.3)	22	331	1 148
Madhya Pradesh	Nov.	71 116	164 (0.2)	6	170	1 216
	Dec.		51 (0.1)	2	53	215

1.3% of all villages in Uttar Pradesh and in only 0.9% in Bihar. However, smallpox was found in 42 out of the 293 municipalities in Uttar Pradesh, in 13 out of 161 in Bihar, and in almost all districts of both states.

The staff had cause for alarm because, in October, smallpox incidence was at a seasonal low. Moreover, the percentage of villages then infected was equivalent to the percentage infected *at any time* during the course of an entire year in the studies by Dr D. B. Thomas and his colleagues in Sheikhpura District in Pakistan (Thomas et al., 1972; see Chapter 14). Until this time, Sheikhpura District had been considered to be the prototype of a district with an unusually high incidence of smallpox in the generally well-vaccinated Indian subcontinent.

Despite the extensive planning and training, assessment revealed that many villages, indeed entire areas, had not been searched, and thus even the high figures recorded understated the problem. With smallpox present throughout both states and in many urban areas, it was apparent that when transmission rates increased, a major epidemic would be possible. In neither state were the health services functioning well and a 3-month period of intensive training and supervision provided little time in which to improve the performance.

The November and December searches were more thorough than the October search. Nevertheless, the number of infected villages which were discovered decreased in both states—more sharply in Uttar Pradesh, suggesting that the new strategy was having an impact. In Madhya Pradesh, geographically India's largest state, the first search was delayed until November because of floods. The results there were highly encouraging. Only 170 outbreaks were found in November and only 53 in December.

Searches in 8 "low-incidence" states revealed only 4 with outbreaks and, during 2 separate searches, fewer than 200 cases were discovered in each (Table 15.18).

Of 10 states which had been expected to be free of smallpox by September, only Andhra Pradesh was found to have had outbreaks, and, in all, only 197 cases were discovered (Table 15.19).

As 1973 ended, it was apparent that large areas of India had remained free of smallpox (Fig. 15.16), and the search programme had confirmed this. In December only 6 states recorded 100 or more cases, and 2 of them—Bihar and Uttar Pradesh—accounted for 84% of the total (Table 15.20; Fig. 15.17). Although the total number of cases recorded in India was 88 114, the highest since 1958, reporting was far more complete than it had ever been.

The autumn campaign had shown that it was possible to mobilize health resources effectively throughout entire states to search for cases and to contain outbreaks. However, with smallpox still widely prevalent in the 4 central states and the period of high transmission again beginning, it was clear that Phase Two of the campaign had to be extended into 1974.

In early January 1974, Henderson had meetings in New Delhi with Indian and WHO staff to assess possible strategies and needs for the coming months. The situation was critical. If the intensified search campaign was to continue, a commitment of additional funds was urgent. Funds earmarked for India in the WHO regular budget were sufficient to cover the campaign activities for 2–3 more months at most. To obtain additional money from WHO was a problem. WHO's budget for smallpox eradication had remained at a constant level since 1967. The funds had been proportionately

<sup>a</sup> Population estimates based on United Nations (1985) data for all India proportionately allocated by state on the basis of the 1971 census.<sup>b</sup> No cases were reported during this period in the union territories of Andaman and Nicobar Islands, Dadra and Nagar Haveli, Lakshadweep, and Pondicherry.

allocated to each of WHO's regional offices in 1967 and the proportions had not changed thereafter. With the certification of eradication in the Americas in 1972, it had been requested that the 1973 allocation for that region should be transferred to the South-East Asia Region. However, the proposal was turned down. Within the South-East Asia Region, some diversion of funds from Indonesia, now free of smallpox, was possible but the amount was not great. Meanwhile, repeated appeals to governments for support had brought generous donations of vaccine but little cash. A further emergency appeal was considered but thought to be futile because governments could seldom respond to such requests in less than several months to a year. Although the programme in India had achieved a momentum which offered hope of success, little could be done without additional resources and there appeared to be no solution forthcoming. Henderson returned to Geneva to consult the newly elected Director-General, Dr Halfdan Mahler. Later that week the WHO Executive Board was to meet. On the agenda was the question of how to use US\$900 000 allocated to China, a new Member State of WHO, which had declined to accept WHO funds provisionally allotted for the support of its health programmes. The Director-General agreed immediately that a cable could be sent

to India indicating that these funds would be used for its smallpox eradication programme, a decision later endorsed by the Executive Board. Another emergency in an apparently never-ending series of financial crises in the programme had been averted.

### **The Darkest Months of the Programme, January-June 1974**

In January 1974 optimism prevailed. Funds were available to continue the programme, case notification was far more complete than ever before, and the search programmes were showing steady improvement in all states. In Bihar, in which the greatest numbers of cases were being recorded and the health services were the least adequate, the programme office reported that 50% more villages had been visited during the third search, in December 1973, than during the first in October. Despite a more extensive search and despite seasonally higher transmission rates, fewer villages with new outbreaks had been found.

The results in Uttar Pradesh had been even better, with the number of newly found outbreaks declining from 1525 in October to 331 in December. Progress in West Bengal was no less encouraging. There, Arita had introduced a new system to document progress in the programme. From October

**Plate 15.10.** Implementing the search programme required extensive field work by national and international staff. **A:** Ram Rakha Arora (b. 1925), an Indian member of the Central Appraisal Team in West Bengal. **B:** Left: Lawrence Brent Brilliant (b. 1944), an epidemiologist from the WHO Regional Office for South-East Asia; right: Anatolij N. Slepushkin (b. 1929), an epidemiologist from the Smallpox Eradication unit at WHO Headquarters.

1973, each newly discovered outbreak was added to a master list as an "active outbreak" and not removed from the list until 4 weeks had elapsed since the last case. At the end of December, there were only 124 active outbreaks in the whole of that populous state. In Madhya Pradesh, the last of the 4 key central states, a search conducted during 7-12 January 1974 revealed only 49 new outbreaks, two-thirds of which consisted of 3 cases or

less. Of 5000 outbreaks discovered in these 4 states between October and December, it was estimated that not more than 1700 were still active. In the other states, the number of reported cases—many of them resulting from importations—remained low. Meanwhile, Bangladesh reported that only 172 of its villages were infected; in Nepal, virtually all outbreaks were said to have resulted from importations.

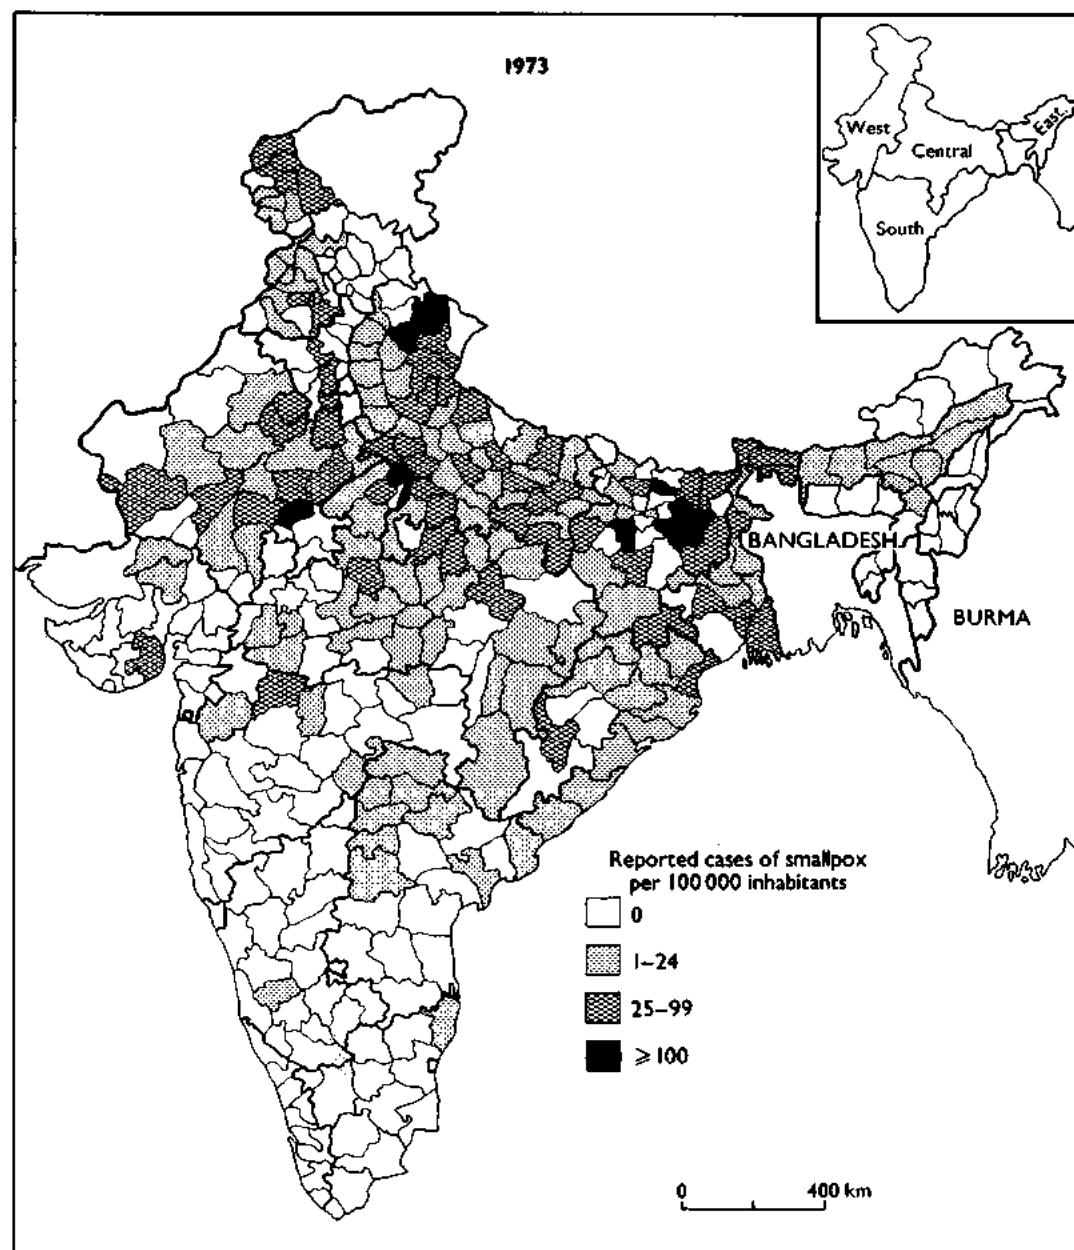

Fig. 15.16. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1973.

### The Dedication of the Smallpox Programme Staff

The commitment and determination of staff who worked in the programme were extraordinary and indeed might well be the subject of a separate book. The meeting in New Delhi on 1 January 1974 of the Indian and WHO Central Appraisal Team and Henderson provides an illustration. All members of the team had been working a 7-day-week for nearly 4 months, travelling to some of the country's most remote and inhospitable areas in a frantic effort to motivate the army of health workers to contain the vastly larger number of outbreaks than anyone had foreseen. All had lost weight and were exhausted, one person had incapacitating renal colic, a second a painful facial herpes zoster infection, a third a serious fungus infection of the foot (which eventually required surgery) and a fourth atypical pneumonia with high fever and pleuritic pain. The only question asked at the meeting was how to find additional resources to sustain the momentum. When Henderson expressed scepticism of their own ability to work, let alone to continue the schedule proposed even if given the needed resources, the reply was simply: "We've considered the question and have decided that things can't get worse; therefore they must get better".

Exemplifying this determination in the field was a 50-year-old Indian professor of social and preventive medicine, Dr T. P. Jain, who was assigned as an epidemiologist in a flood-stricken area of Assam. Investigation and containment of many of the outbreaks required wading from house to house in areas in which leeches were legion and snakes a problem. A devout member of the Jain religion, he had requested a week's leave to attend ceremonies in another state commemorating the 2500th birthday of Mahavira, founder of the religion, a long-anticipated and sacred event. Another epidemiologist, arriving in the area to check the existing outbreaks in Jain's absence, found him waist-deep in water trudging from house to house, unwilling to leave for even a day so long as smallpox persisted in his area.

The commitment of the government to the programme was demonstrated early in 1974, when Dr Sharma was promoted to the position of Commissioner of Rural Health while retaining responsibility for smallpox eradication. Dr Sharma was widely known and respected among professional health staff and politicians alike for his expertise in the field of communicable diseases and for his executive ability. He had the full support of the Minister of Health and Family Planning, Dr Karan Singh. His commitment to the surveillance-containment strategy was total, and this he communicated to national and state officials on frequent visits to the field. It was important that he did so because the Director-General of Health Services, to whom he was subordinate, adhered to the traditional view that only a thorough mass vaccination campaign could succeed in eradicating smallpox, a view he expressed on frequent occasions. In part because of this contradictory advice, state officials in Bihar and occasionally in Uttar Pradesh were to call periodically for the suspension of search and containment activities in favour of total mobilization for a mass campaign to vacci-

nate everyone in the state. The mass vaccination approach was more easily understood and although it had been demonstrably unsuccessful in the past, there was the belief that if the health personnel were *really* properly organized and motivated the objective of 100% vaccination could be achieved. Dr Sharma's appointment ensured that the basic surveillance-containment strategy would be sustained.

A summary statement appearing in a WHO South-East Asia Regional Smallpox Surveillance Report (4 February 1974, unpublished) is indicative of the optimism prevailing at the beginning of 1974:

"The tremendous increase in smallpox activities in the region since October 1973 has had its impact. Smallpox is diminishing in many areas at a time when it traditionally increases ... proving that smallpox transmission can be interrupted even at the height of the smallpox season. Within a few weeks a decrease in the transmission of smallpox can be expected ... If programme activities can be maintained or increased, most areas in India and Bangladesh could interrupt transmission before the monsoons."

Fig. 15.17. India: number of reported cases of smallpox, by region, 1968–1975. (Population data for 1971 from Basu et al., 1979.)

BY COURTESY OF R. S. AGARWALA, 1974

**Plate 15.11.** Mudi Inder Dev Sharma (b. 1919), the Commissioner of Rural Health for India, vigorously and enthusiastically supported the programme from early in 1974 through extensive travel and personal inspiration. He is using the WHO smallpox recognition card to ask villagers in Uttar Pradesh State about possible cases of smallpox.

It was to be the last optimistic statement for many months.

In February 1974, the fourth search was conducted in Bihar. It revealed 1170 new outbreaks in villages and 18 in urban areas, almost 3 times the number (405) found in December, and more than twice as many cases

as in January—10 697 as against 4816 (Table 15.21). The most seriously affected areas were the eastern districts. From here, smallpox began to spread to West Bengal (65 importations by mid-February) and to Nepal (11 importations).

Additional Indian and WHO epidemiologists were hurriedly recruited and assigned to Bihar. The fifth search (11–16 March) revealed 2374 new outbreaks, double the number found in February: more than 7000 cases were recorded during the search period (Fig. 15.18). By the end of the fifth search, there were 3682 active outbreaks in the state. Containment policies at this time called for the vaccination of residents only in the 20–30 houses adjacent to infected households. Even so, there were too few surveillance and containment teams to be able to visit more than a small proportion of the outbreaks, which were detected in many areas, and even the minimal containment measures were poorly executed. Desperate for additional help to supervise the search and containment programme, senior programme staff decided to recruit recent medical school graduates and, after a special training programme in New Delhi, 40 “junior doctors” were assigned to field work in Bihar. Eventually 140 were to participate (Jha & Achari, 1975).

Epidemic smallpox in Bihar was a problem of formidable proportions, and the occurrence of one natural or man-made calamity

<sup>a</sup> Population estimates by states are based on United Nations (1985) data for all of India proportionately allocated by state on the basis of the 1971 census.

<sup>b</sup> No cases were reported during this period in the union territories of Andaman and Nicobar Islands, Dadra and Nagar Haveli, Goa, Daman and Diu, Lakshadweep, and Pondicherry.

after another further hampered the eradication effort. Indian Airlines workers went on an extended strike, making it difficult to ship vaccine and for senior personnel to travel. The railways began to be extensively used until railway workers likewise went on strike. Meanwhile, the international oil crisis had developed and, in April, petrol costs in India doubled and shortages occurred. Drought in southern Bihar, sufficiently severe to require international assistance, resulted in the migration of large populations of refugees seeking food and spreading smallpox. This was soon followed by the most severe floods in a decade in northern Bihar and even more refugees fleeing in search of food and refuge. Civil disorder and political disturbances began to occur throughout Bihar and, over large areas, government authorities were totally occupied with maintaining law and order. Throughout this period, heroic efforts were made to ensure an adequate flow of supplies and to stockpile materials such as

vaccine and reporting forms in anticipation of expected shortages; however, most supplies were barely adequate to meet the current needs.

That the programme in Bihar functioned at all was remarkable and for this due credit must go to its Smallpox Programme Director, Dr A. G. Achari, a conscientious and tireless worker who, with the officers of the Central Appraisal Team, Dr Foege and Dr Dutta, sought valiantly to mobilize a lethargic health staff and to sustain morale among the Indian and WHO epidemiologists, who were overwhelmed by the explosive spread of smallpox.

When it seemed that little else could possibly go wrong, the health workers in Bihar threatened to go on strike. Dr Achari, Dr Dutta and Dr Foege sought desperately to develop a contingency plan but with little support. The observation of one district health officer was characteristic of the attitude of some supervisory health staff: "If we

Fig. 15.18. Bihar State: number of reported cases of smallpox, by week, showing results of special searches, January–May 1974.

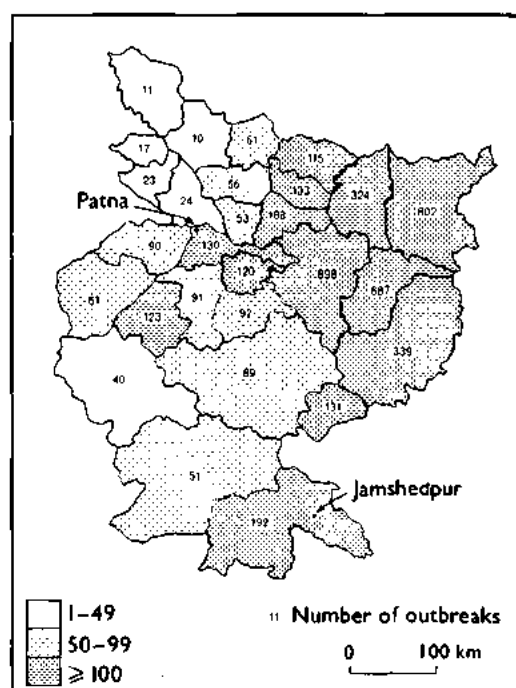

Fig. 15.19. Bihar State: number of active outbreaks of smallpox, by district, as of 5 May 1974.

don't have a strike, we don't need a contingency plan; if we do have a strike, it is no longer my responsibility."

The sixth search in Bihar (29 April–4 May) recorded 2658 additional outbreaks—the number of active outbreaks increasing to 4921. More than 7% of all villages and municipal areas in the state were infected, the most heavily afflicted being in the north-east (Fig. 15.19), where, in 3 districts, 25% of all villages were infected.

India's Director-General of Health Services, still an advocate of mass vaccination, became increasingly alarmed and advised Bihar's Minister of Health to withdraw staff from the infected areas and to begin mass vaccination campaigns in the areas still free of smallpox to prevent them from becoming infected. Dr Sharma, learning of this only after the minister in Bihar had begun to take action, protested direct to India's Minister of Health and Family Planning, Dr Karan Singh, and together they flew to Bihar to intercede. The Bihar minister rescinded his order. In an epidemic as extensive as that occurring in Bihar, some of the Indian and WHO programme epidemiologists began to speculate that Bihar might represent a special case in which the now well-tested surveil-

lance and containment strategy might not be applicable.

Throughout May and into early June, the epidemic continued to intensify. With daytime temperatures normally exceeding 40 °C, field work became ever more difficult, morale began to deteriorate and, again, the question of a return to state-wide mass vaccination arose. The minister was more resolved than before and, in the June meeting of state and district programme officers, strongly advocated this approach. Senior programme staff argued in vain, until an Indian physician, working in one of the districts, pointed out in a deferential manner that he had grown up in a village and there, when a house was on fire, they put water on that house and not on all houses in the village. The minister reluctantly agreed to defer a mass vaccination campaign for one more month but only on the understanding that if no apparent progress had been made by then, mass vaccination would be initiated. Senior staff hoped that, even if containment were less than optimum, the seasonal decrease in transmission would partially stem the epidemic and so preserve what they believed to be the only possible effective strategy—surveillance and containment.

WHO/C. HENRIQUET, 1975

**Plate 15.12.** Karan Singh, Minister of Health and Family Planning of India from 1973 to 1977, provided strong political support for the programme and for the surveillance-containment strategy.

In the other states of India, the situation was better than in Bihar but not so good as had been expected in February. Uttar Pradesh was the next most heavily infected state. The numbers of reported cases and outbreaks had risen steadily since January, although less precipitously than in Bihar. A peak of 1905 active outbreaks was reached in May, with 8337 cases reported that month. Outbreaks were reported from 442 (51%) of the state's 875 primary health centres and in 47 of its 55 districts (Srivastava & Agarwala, 1975). However, 82% of the outbreaks occurred in only 15 districts, primarily in eastern Uttar Pradesh, where their large number precluded the taking of effective containment measures. Elsewhere in the state, with the support of the Director of Medical and Health Services and Family Planning, Dr G. P. Srivastava, the health staff had begun to function well.

In West Bengal, the number of active outbreaks increased steadily, from 124 in December to 556 following the seventh search in mid-April. However, more than 75% of the outbreaks took place in only 5 of the state's 16 districts, and here village volunteers began to be recruited and trained for containment operations, an effective practice later adopted in other states. The increase in the number of outbreaks in West Bengal was largely accounted for by importations, mostly from Bihar. Between January

and May, programme staff documented 386 imported outbreaks, and others occurred as a result of spread from these importations.

Importations, principally from Bihar, Uttar Pradesh and West Bengal, accounted for an increase in the number of cases in Madhya Pradesh, Maharashtra and Orissa. Each state worked diligently and effectively to discover and contain the outbreaks as rapidly as possible, but by May, both the smallpox eradication staff and the general health service personnel were reaching a critical point of fatigue and frustration. Meanwhile, the eastern states, hitherto all but free of smallpox, experienced a sharp increase in the number of cases, resulting from importations from Bangladesh, Bihar and Uttar Pradesh. This was cause for additional alarm because, in the eastern states, health services were generally less extensive and not much better organized than those in Bihar. Although they were not populous states, road and rail services were poor and both search and containment activities were difficult to organize and to execute.

The unexpected and explosive epidemic of smallpox in Bihar and its spread to other states had required the mobilization of far more Indian and WHO epidemiologists (see Table 15.16) than had been foreseen and had necessitated the emergency purchase of more vehicles and supplies of all types than had been planned. By April, funds to support the smallpox programme were again at a low level. Requests were made to numerous governments for additional finances; few showed any interest and no country indicated it was in a position to act quickly in answering an appeal. Privately, many expressed scepticism about the programme's prospects of success. The reaction was not surprising in view of the fact that the number of cases of smallpox recorded in India in the spring of 1974 was the largest for nearly two decades. WHO's frequent appeals in the past for funds to bolster its malaria eradication campaign, and the continuing setbacks in that programme despite infusions of ever larger sums of money, were well remembered. Once again, the programme approached a critical point, but, unexpectedly, substantial help materialized from a new source, the Swedish International Development Authority (SIDA). In a casual conversation with the Personnel Officer of the WHO Regional Office for South East Asia—an official of Swedish nationality—Dr Grasset learned

1980

**Plate 15.13.** Jarl E. Tranaeus (b. 1923), Head of the Development Co-operation Office of the Swedish Embassy in New Delhi from 1973 to 1978, persuaded Swedish authorities and the Indian government's Planning Commission of the need for substantial additional assistance to the smallpox eradication programme at a crucial moment.

that SIDA planned to examine alternative uses for Swedish funds which had become available because of the cancellation of another project in India. Discussions promptly followed with Mr J. Tranaeus, at the Swedish Embassy in New Delhi. Convinced, as few others were, that an effective and well-directed campaign was in progress whatever the smallpox incidence might suggest, he persuaded the Planning Commission of the government of India, as well as his superiors in Stockholm, of the merits of the programme. Within a few weeks, a memorandum of agreement had been signed on behalf of the governments of India and Sweden which made available to

WHO US\$2.8 million in support of the smallpox programme. With Mr Tranaeus's continuing enthusiastic interest, SIDA was eventually to provide US\$10 million to the programme. The government of India also increased its own central allocation of funds. For 1974, a sum of US\$13 million was made available for field operations.

Time was required to effect the necessary transfer of funds, but the Division of Budget and Finance in WHO Headquarters readily agreed to permit funds to be obligated even though they were not yet in hand. Meanwhile, the administrative staff in the WHO regional office were experiencing difficulties, because of the substantial expansion in the number of personnel in the programme receiving a stipend from WHO, the larger numbers of imprest accounts to be handled and the need to procure a greater volume of supplies (Table 15.22). It was essential that additional personnel should be recruited and that budget and finance operations should be established for the programme. The Center for Disease Control (formerly the Communicable Disease Center) in Atlanta, which was already providing many field epidemiologists, responded to this need by sending its most capable senior administrative staff to help to bring some order into an increasingly chaotic administrative situation. Beginning with the Center's Deputy Director, Mr William Watson, an exceptionally imaginative group of administrators worked tirelessly with the group of no less talented WHO administrative staff to provide essential services in support of the field staff.

Although the smallpox epidemic was featured more often and with greater prominence in Indian newspapers, little was known of the problem outside the country. However, in May 1974, the epidemic became international news. On 18 May 1974, India tested its first atomic device in an underground explosion in Rajasthan. At that time, the smallpox epidemic was at its height, more than 11 000 cases being reported in a single

**Table 15.22.** India: principal supplies and items of equipment provided by WHO, 1970-1976<sup>a</sup>

Item	1970	1971	1972	1973	1974	1975	1976	Total

<sup>a</sup> Between 1972 and 1976, it is estimated that WHO, in addition, arranged to print and distribute the following material: approximately 31 million forms for use in reporting and in search and containment operations; 500 000 booklets for use in outbreaks and in market searches; 400 000 posters; 1 million smallpox recognition cards; and 500 000 other guides and miscellaneous publications.

week. International news reporters who had flown to India to cover the atomic test arrived just as the smallpox epidemic hit the headlines in the local press; international media coverage of both events was extensive. Programme staff repeatedly explained that more complete reporting accounted in major part for what appeared to be the largest epidemic for many years, but scepticism was prevalent and understandable.

Although the problem in Bihar was serious, the eradication programme throughout India was steadily improving and gaining momentum. Week-long village-by-village searches were being performed each month throughout the high-incidence states and less frequently in the others (Table 15.23). The number of those engaged in the searches was increasing (Table 15.24).

As serious and frustrating as the situation appeared, yet another disaster aggravated it—the Jamshedpur epidemic in Bihar State. Its discovery resulted from investigations in

Madhya Pradesh. Special efforts had been made to interrupt transmission in Madhya Pradesh. It was one of the 4 central states considered to be of highest priority, and was geographically the largest state in India, with a population of 46 million. Most of the outbreaks which had been discovered during the autumn searches were in the northern and eastern districts of the state, bordering on Bihar and Uttar Pradesh. The December 1973 search had revealed only 215 cases and 53 new outbreaks. By the beginning of March 1974, and after 5 monthly searches of its 10 million households, smallpox appeared to be present in only a single, geographically limited focus, in a tribal area and one of the least developed parts of the state.

In late March 1974, however, reports of smallpox outbreaks began to arrive from many areas of Madhya Pradesh which had been considered to be smallpox-free. Investigations revealed these to be the result of recent importations from the neighbouring state of Bihar. The source of infection of many was traced to an industrial complex in southern Bihar: Jamshedpur in Singhbhum District. *Adinassis* (tribal people) often travelled 300–800 kilometres to Jamshedpur from their homes in Madhya Pradesh in search of seasonal employment. If they became ill with fever, they returned to their native villages, where many subsequently developed rash and spread smallpox to others.

Dr Brilliant was dispatched to Jamshedpur in late April to assess the situation. He found a major problem of unexpected magnitude.

#### *The epidemic in Jamshedpur, Singhbhum District, Bihar*

The Jamshedpur industrial complex is one of India's most important steel-producing areas, its prosperity contrasting sharply with economically depressed neighbouring areas of southern Bihar, eastern Madhya Pradesh

BY COURTESY OF TATA INDUSTRIES

**Plate 15.14.** The office of Tata Industries, Jamshedpur, became the smallpox eradication headquarters for Chotanagpur Division, Bihar State.

and northern Orissa. As such, it attracted numerous seasonal workers, beggars and transients.

The special investigation began in early May. The District Medical Officer of Singhbhum disclosed that during the preceding 6 weeks, he had received 125 notifications of outbreaks in other districts of Bihar and in other states which were suspected of having originated in his district, and that 12–15 notifications were then being received daily. Little action had been taken, the government health structure in this district being poor. In addition to 27 primary health centres that reported to him, all of which were then known to have smallpox cases, there were 15 autonomous and separately administered health units in Jamshedpur (population, 800 000). The health units included small company towns, corporations, large colonies of railway employees and others. No one was charged with the task of reporting cases among the large migrant population, and the railways denied all responsibility for the reporting of cases from the areas they administered. Half the health units were found still to be using rotary lancets.

At the industrial complex, a group of heavy industries of the Tata group, officials professed ignorance of the problem but immediately agreed to provide help in a search of the city and of 1760 villages within a 45-kilometre radius. In a search that took place in mid-May, 50 physicians, 200 paramedical supervisors and 900 searchers discovered 1479 cases in the city and 726 cases in the 456 villages found to be infected (Basu et al., 1979). An intensive programme of containment and case detection was immediately undertaken. This involved, in addition to government and WHO health staff, personnel and transport provided by 7 of the Tata industries as well as voluntary organizations, including the Rotary Club, the Lions Club, the Bihar Flying Club, the local blood bank and the All-India Women's Council (Bharucha, 1975). All bridges and major roads were barricaded and no one was permitted to pass unless vaccinated. A special programme dealt with railway travellers, especially third-class passengers, of whom perhaps one-third travelled without tickets. Trains were diverted to special platforms, which permitted all passengers to be checked

Fig. 15.20. Spread of smallpox from the Jamshedpur urban industrial complex to the rest of India, 1974.

when boarding or leaving a train. Check-points were established at bus stations, and employers ensured that workers and their families were vaccinated. Meanwhile, the containment of all known outbreaks began, an effort which in fact necessitated house-to-house vaccination of the entire urban complex and most of the surrounding villages.

Two months were required to bring the epidemic under control. Meanwhile, 300 outbreaks and at least 2000 cases occurred in 11 states of India and in Nepal as a result of

travel from Jamshedpur (Fig. 15.20). The area most affected was Bilaspur District (Madhya Pradesh), with 484 cases in 72 villages.

#### A Redoubled Effort, June–December 1974

Early June 1974 was the psychological low point of the Indian smallpox eradication programme, if not of the global Intensified Programme itself. A 9-month intensive campaign had been conducted throughout India

Fig. 15.21. India: number of districts reporting cases of smallpox, by month, 1971-1975.

with senior staff and numerous field staff working 7 days a week. Despite the large expenditure of money and effort to date, and despite what appeared to be an increasingly successful effort in surveillance and containment activities, there were 8664 known outbreaks. Moreover, up to the end of May, India had already recorded 116 188 cases, a number greater than that reported for the entire world during any of the preceding 6 years of the Intensified Programme. Cases were reported in May from nearly one-third of the districts in India, of which 80 reported 50 cases or more (Fig. 15.21). Many areas of India remained free of smallpox or had only a few outbreaks resulting from importations (Fig. 15.22), but the epidemic wave then surging through Bihar seemed to be moving both east and south. It was clear that the efforts made so far in Bihar had been inadequate to contain smallpox, and the states which appeared to be the next candidates for epidemic smallpox—Orissa to the south and the states to the east—had health services which were not much better in quality than those in Bihar.

During June, with the beginning of the monsoon period, smallpox transmission normally declined in India and the number of outbreaks diminished. However, with the disease so widely seeded throughout Bihar and adjacent areas, it was clear that unless a concerted effort were made to contain the outbreaks during the summer, smallpox would remain widely disseminated at the commencement of the next season and the

experience of the spring of 1974 would be repeated. Activities of all types usually diminish in India during the summer months—the hottest, the most humid and the most difficult months of the year in which to work. A staff which had toiled to the point of exhaustion between September and May would have to mount one more effort.

On 17 June 1974, the Central Appraisal Team met the Secretary of Health and the Director-General of Health Services to discuss an emergency programme for the whole of India, but especially for Bihar. It was decided to increase the number of special epidemiologists from the 50 who were in the field at the time to more than 100. WHO would initially provide 12 additional international epidemiologists, and 6 non-medical surveillance officers; the government of India would attempt to recruit 40 epidemiologists. If that proved impossible, WHO would try to obtain the services of more international epidemiologists.

Six central-level surveillance teams would be established which would respond to emergency smallpox problems as they developed. State surveillance teams, hitherto restricted in travel to the state in which they were assigned, would be directed to cross state borders whenever necessary to seek the source of infection of outbreaks.

Three hundred additional containment teams would be recruited, each to be headed by recent Indian medical graduates. A further 375 Jeeps would be purchased or hired. To

fund these activities, SIDA offered additional financial assistance, which was rapidly made available.

It was recognized that special efforts would be required in Bihar. Following consultations between the staff of the WHO regional office, the Governor and the State Health Minister, the Chief Secretary of the State of Bihar sent a special letter to all district magistrates, informing them that as from the

end of June they and the block development officers would assume responsibility for the conduct and organization of the campaign in their districts. Dr Achari would continue in his role as State Smallpox Eradication Programme officer but more effective senior administrative staff would replace the health service staff in bearing primary responsibility for the programme.

The president of Tata Industries was

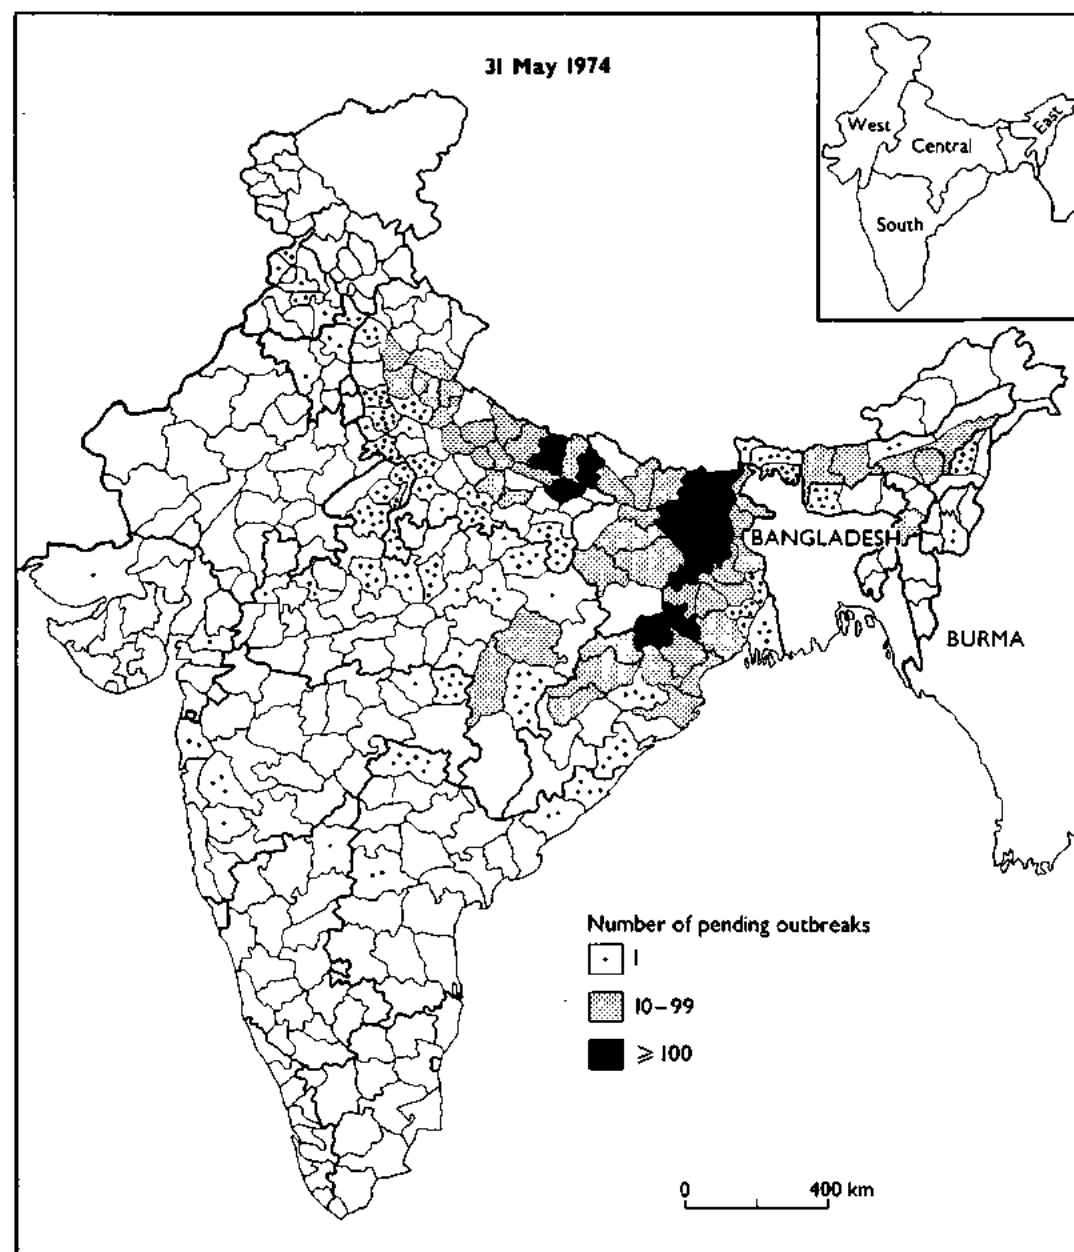

Fig. 15.22. India: number of pending outbreaks of smallpox, by district, as of 31 May 1974.

### The Situation in India as Seen in June 1974

Memorandum, dated 24 June 1974, from the Chief of the WHO Smallpox Eradication unit to all smallpox eradication staff:

"The epidemics of smallpox now occurring in Bihar, eastern Uttar Pradesh and adjacent areas have been the subject of world-wide press interest during the past two weeks with many articles appearing in all major newspapers and news magazines. Providing perspective on the problem has not been easy. While there is no question but that Bihar and eastern Uttar Pradesh are heavily afflicted and represent now the "epicentre" of the global problem, the fact of a far more active programme and more complete reporting unquestionably magnifies the severity of the problem when comparing this year's and last year's data. Whatever the relative magnitude of the problem, it is clear that the most critical battle of the entire programme is now being fought on the Indo-Gangetic plain of Bihar, Uttar Pradesh and the adjacent states. Our success in these efforts over the coming months will be determining in regard to the goal of global eradication.

"The reporting of large numbers of cases as is now the case in Bihar, eastern Uttar Pradesh and adjoining areas, is of real concern but, at the same time, it may also be regarded as an encouraging sign. Unless outbreaks are found, they cannot be controlled. And one must recall the experience in Brazil when, in 1969, surveillance was first introduced into the programme. Smallpox incidence abruptly rose that year to reach the highest level in almost a decade, only to fall to '0' less than a year later. Can we do the same in these other problem areas? Unquestionably we can, provided there is full government support at all levels and that every effort continues to be made to find all cases and outbreaks and to contain them.

"While the epidemics in India have captured the headlines, equally newsworthy are the spectacular achievements in Pakistan. It is apparent that staff at all levels of the programme now realize that eradication is imminent and with this realization has come an even more energetic burst of activity."

approached for help in dealing with smallpox in the 6 southern districts of Bihar comprising Chotanagpur Division. He agreed to assist and the company's Board of Directors approved the expenditure of 7.2 million rupees (US\$900 000) and the assignment of personnel and vehicles. An unusual semi-autonomous public and private sector programme was created in this division, involving personnel and equipment from WHO, Tata Industries, the government of India, the state of Bihar, and OXFAM, a private voluntary organization. The consortium participating in the Chotanagpur Division programme was to function capably and with remarkable cooperation over the following 12 months.

Deficiencies in the containment of outbreaks had proved to be a serious weakness of the programme in most states, particularly Bihar and Assam. Where smallpox outbreaks were few, state surveillance teams had usually assisted local staff in their investigation and in the vaccination of village residents. Where smallpox was widely prevalent, procedures

called for the detection of all cases in the area and the vaccination of those in the 20-30 nearest households. The names of any absent household members were supposed to be recorded and the village visited on a later occasion to ensure that all were vaccinated. This directive was rarely followed, however. In many areas of the world, and indeed in many parts of India, simple containment measures had sufficed to stop transmission. In the more densely populated parts of India, however, they proved ineffective. Many persons left their homes during the day to go to the fields, to market or elsewhere; some who objected to or feared vaccination simply hid themselves and their children when the teams were in the villages; many visited relatives and friends, including those with smallpox, in other villages. The result was that even after intensive containment vaccination, numerous susceptible persons remained and smallpox transmission persisted.

It was therefore decided to systematize the containment activity in a manner that could be readily understood and widely applied and

BY COURTESY OF TATA INDUSTRIES

**Plate 15.15.** One of the 56 surveillance teams in Chotanagpur Division, Bihar State, setting up camp in a tribal village. The programme in Chotanagpur, one of the most seriously affected areas, represented an unusual co-operative effort of groups from the public and private sectors.

that was subject to verification by a supervisor. "Containment books" were designed, printed and distributed in August 1974. One book was used for each outbreak. The name of each person in each of 500 houses surrounding an infected household in a rural area (1000 houses in an urban area) was to be listed in the book and repeat visits made to the village until all persons had been vaccinated and the fact duly registered in the book (Sharma & Grasset, 1975). In a separate section of the book, information regarding each case was recorded.

Three specific standards were also established at this time as indices of the effectiveness of, respectively, surveillance, containment, and outbreak investigation activities. The provision of standards by which a programme in any area could be measured was thought to be helpful in improving the quality of supervision. An indication of the degree of effectiveness of surveillance was the lapse of time between the onset of the first case and the detection of the outbreak. The detection of at least 75% of outbreaks within 14 days of the onset of the first case was felt to be attainable. If adequate containment were performed, all susceptible contacts would be vaccinated and none should develop smallpox once vaccinal immunity had developed say, after 7-12 days. Assuming that it would take several

days to identify and vaccinate susceptible persons, it seemed reasonable to establish a second goal—namely, that no cases should develop more than 17 days after an outbreak was detected. The quality of the investigation of an outbreak was more difficult to measure, but such quantification was considered important because experience had shown that the least well performed part of an investigation was usually the identification of the source of infection. The concept that each individual with smallpox must have been in face-to-face contact with another individual with smallpox just 7-17 days before onset was a surprisingly difficult concept for many to grasp. On investigation forms, many simply listed "sporadic" as the source of infection. To identify the source, however, was vital because often other, as yet undiscovered, outbreaks were unearthed in this manner. Thus, the third goal called for the identification of the source of the outbreak in 90% of outbreaks, a level of success which had been achieved by competent epidemiologists in other areas.

The measurement of progress based on the number of the then existing infected villages and urban *mohallas* (sections of a city) had been initiated in October 1973 in West Bengal and had been introduced in some other states as well, particularly those with a low incidence of smallpox. In June 1974,

### The Problem of Beggars

The containment of outbreaks among beggars proved to be an exceptionally difficult problem requiring imaginative and administratively unorthodox solutions. The isolation of beggars with smallpox in their homes was impossible because most were transients. In fact, isolation either in a house or in a hospital was refused because both the beggars and their families were dependent on begging for their livelihood. Even those actively ill with smallpox travelled from village to village shouting for alms, as was their custom. During 1973, a number of instances were documented in which infected beggars had transmitted smallpox to a dozen or more people and had been the source of many widely dispersed outbreaks.

In 1973 an epidemiologist wrote to propose that beggars with smallpox and their families should be given food and lodging until they recovered. The proposal was rejected by WHO regional office administrators and senior Indian staff, who foresaw this as a precedent to providing support to a legion of beggars. Undeterred, Dr Stephen Jones, a free-spirited American epidemiologist, used his imprest account funds to do just this and submitted a bill of 1800 rupees for the hiring of a house, the purchase of rice, a broom and various other supplies to house a family of beggars. Anticipating trouble in explaining the outlay to WHO's finance officer, Dr Grasset and Dr Foege decided to pay the relatively small bill themselves but argued more aggressively for a change in policy. Eventually, the practice was accepted. During succeeding months, hundreds of beggar families with smallpox were supported in this manner and effective containment of the outbreaks was achieved.

uniform definitions for this method of measurement were developed and it was formally adopted throughout India. Any village or *mohalla* in which a case had occurred within the preceding 4 weeks (subsequently extended to 6 weeks) was considered to be the site of a "pending outbreak". This concept recognized the potential for the spread of smallpox from the patient to susceptible contacts throughout the period concerned and the need to check the outbreak repeatedly to ensure that transmission did not continue. A list was kept in each primary health centre and each district (later, each state) showing the name of the infected village or *mohalla*, the date of onset of each case, the date of discovery, the date on which containment began, the source of infection, and the dates on which supervisory personnel had visited it. The outbreak was not removed from the list until the site was visited and searched again, not less than 4 weeks (later, 6 weeks) after the onset of the last case.

As at the end of June 1974, there were 6401 pending outbreaks in 17 states and Delhi Municipal Corporation (Table 15.25).

With additional resources and an increased complement of supervisory personnel, state-wide search and containment programmes continued throughout the summer. Most of the resources were assigned to Assam, Bihar,

Uttar Pradesh and West Bengal, in which searches were conducted monthly. In Bihar alone, 35 national and international epidemiologists and more than 100 state epidemiologists and paramedical personnel assisted state, district and local health personnel (Jha & Achari, 1975); in Uttar Pradesh, there were 27 national and international epidemiologists and 19 state surveillance teams (Srivastava & Agarwala, 1975). Most other states conducted one search during this period, although some conducted two. The number of pending outbreaks began to decline sharply, and with fewer outbreaks surveillance teams were able to provide increasingly better supervision of search and containment activities. The quality of both procedures rapidly improved. In addition, the teams devoted more time to visiting markets and schools to inquire about rumours of possible cases. The number of pending outbreaks decreased to 4606 at the end of July and to 3267 at the end of August. The first hopeful note since February was sounded on 26 August in a WHO South-East Asia Smallpox Regional Surveillance Report: "The opportunities for interrupting smallpox transmission in India, Nepal and Bangladesh are better than at any time since the programme started."

By the end of September, there were only 2124 pending outbreaks, of which 1727

<sup>a</sup> No outbreaks were recorded in the union territories of Andaman and Nicobar Islands, Arunachal Pradesh, Chandigarh, Dadra and Nagar Haveli, Goa, Daman and Diu, Lakshadweep, Mizoram and Pondicherry.

(81%) were in Bihar (Table 15.25; Fig. 15.23). The north-eastern districts of Purnea and Katihar in Bihar had more than 600 pending outbreaks, but in only 8 other districts were there more than 50. Almost none were to be found in all of southern and western India. In September, 4674 cases were reported, one-tenth the number recorded in May.

The staff were optimistic but still concerned. The analysis of data from previous years indicated that some increase in transmission occurred at the beginning of October, coinciding with an increase in the numbers of persons travelling from place to place to attend festivals and marriages. Thus, there was a heightened concern about the spread of smallpox over greater distances. Moreover, active outbreaks persisted in 50 municipalities which were recognized to be important sites of dissemination to rural areas. Finally, in Assam, the number of pending outbreaks had actually increased from a low of 50 in August to 64 in September; in this state, field operations were greatly hampered by floods, a poor trans-

portation network and a less than adequate health service. Its neighbour, Bangladesh, appeared to pose no threat, since there were only 163 infected villages in the country at the end of September, a competent programme was in place and the numbers of reported cases and outbreaks were declining as rapidly as in India. In Nepal, to the north, only 4 outbreaks were detected in September 1974.

Additional measures were implemented in October to strengthen surveillance and containment. In all urban areas with active outbreaks, a house-to-house search was conducted every 2 weeks. Additional personnel were assigned to work in Assam. Perhaps of greatest importance was the decision to offer throughout India a reward for the notification of a previously unreported outbreak of smallpox in which a case had occurred within the preceding 6 weeks. This, it was hoped, would permit earlier detection of cases and discourage the suppression of reports which, despite all efforts, remained a problem in some areas. In addition, smallpox cases were sometimes hidden by villagers who held

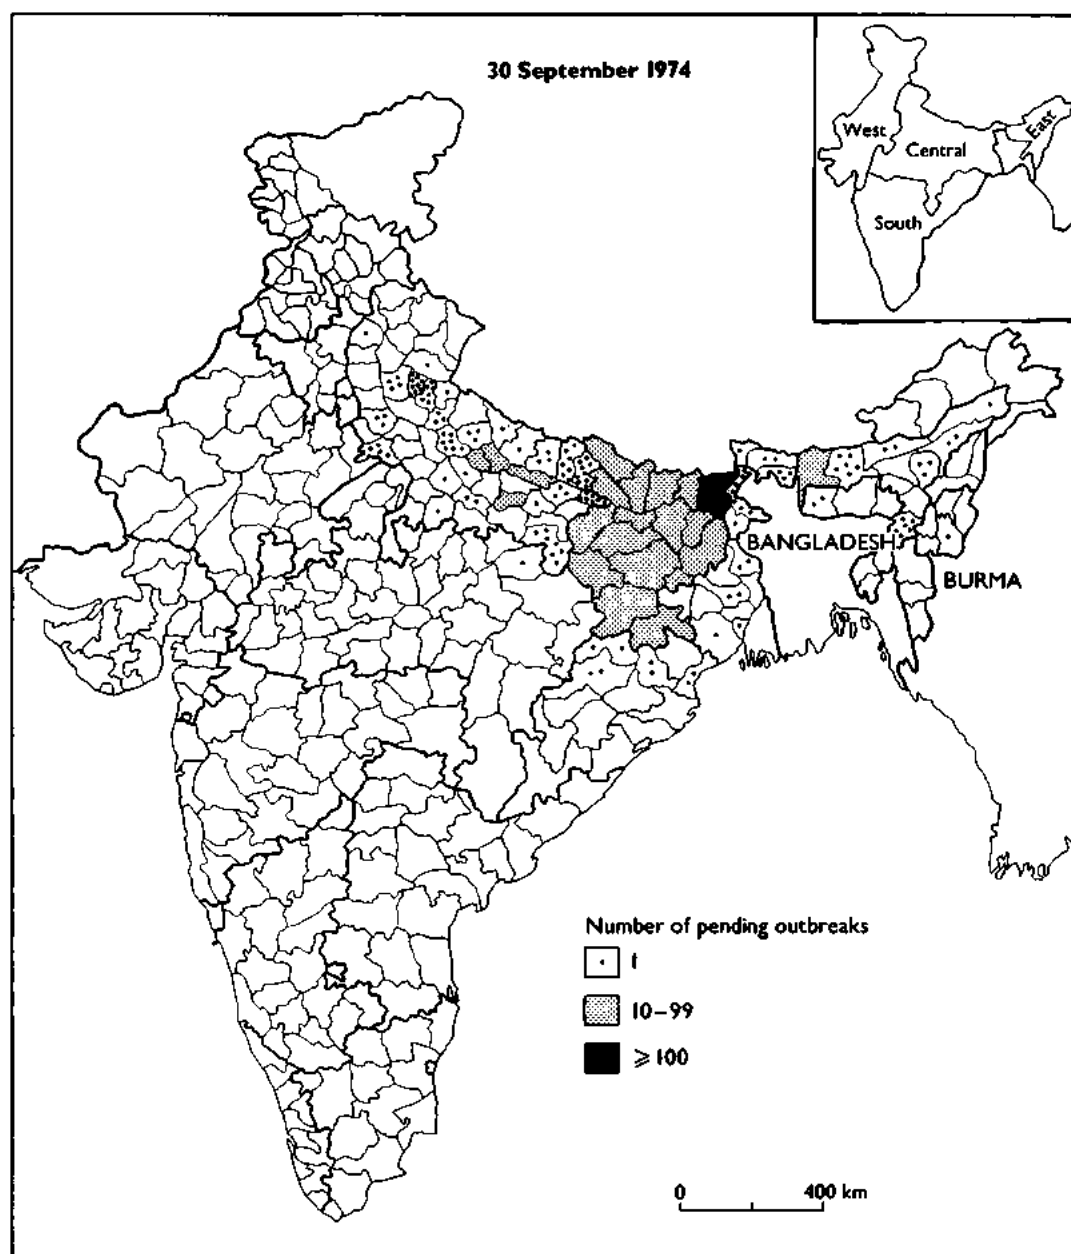

Fig. 15.23. India: number of pending outbreaks of smallpox, by district, as of 30 September 1974.

religious objections to vaccination or feared that patients might be removed to hospital. The offer of a reward had originally been proposed in 1972 in areas with a low incidence of smallpox, but many health officials had been reluctant to adopt the practice, fearing that it would create a precedent with regard to the reporting of cases of other diseases. However, as has previously been described, 5 of the southern

states began offering rewards of 10-25 rupees, following the extensive suppression of reports which resulted in the Gulbarga (Mysore) outbreak in 1972. Early in 1974, some other states that had a low incidence or were thought to be smallpox-free also began to offer a reward, which was now increased to 50 rupees. The inducement had not been particularly effective, however, because information about the reward was not widely

### Market Searches

Surveys in the traditional weekly markets, held throughout India, were especially useful in detecting cases of smallpox. It was found that 2 searchers could readily question 300–500 market visitors in the course of a working day (Basu & Khodakevich, 1978b) and obtain information about cases in villages 10–20 kilometres distant. It was a technique widely employed by surveillance teams.

Posters showing a smallpox patient and announcing the reward for reporting a case were posted at the entrance to the market and in tea-shops. At each entry point 2 workers were stationed, one of whom asked those entering the market if they knew of cases and which village they were from; the second worker recorded the information. Later, the searchers moved to the tea-shops to continue the questioning. The investigation of all reported or rumoured outbreaks was undertaken the following day.

To assess how effective the market search technique had been, a special study was conducted in a mountainous area of Assam (Khodakevich & Rao, 1978) in January 1976. In a district comprising 695 villages scattered over an area of roughly 15 by 55 kilometres, 7 markets were searched to determine whether outbreaks occurring over the preceding 3 years could be detected. The searchers were health workers who had not been associated with the programme and had no information about previous smallpox in the area. Visitors to the market reported 64 villages as having been infected with smallpox during the preceding 3 years. Investigation revealed that 18 of the villages were in another district, 2 had outbreaks in 1970, 2 had outbreaks of chickenpox, and in 8 others no evidence of outbreaks could be found. The remaining 34 villages in which smallpox was reported to have occurred included all 13 villages which had had outbreaks in 1975, 17 out of 32 of those with outbreaks in 1974 and 4 out of 13 of those with outbreaks in 1973. Although the market searches did not detect all outbreaks, they served to provide a great deal of information at a minimum cost in manpower.

disseminated by the health workers, who wanted to claim the money for themselves. To overcome this problem, it was decided to offer 50 rupees to the person first reporting a previously undiscovered outbreak and 50 rupees to the health worker who received the report.

Containment measures were also strengthened as some surveillance-containment teams, which now had fewer outbreaks to contend with, began to stay in infected villages overnight to ensure that all residents were vaccinated. One or two local inhabitants, termed "watchguards", were hired to stay at each infected house to prevent the patient from leaving and to vaccinate anyone who could not be dissuaded from visiting. Eventually, 4 watchguards were engaged to guard each house with a patient, 2 of them working during the day and 2 at night. This meant that if one watchguard had to absent himself, one would remain on duty. When it was found, in some areas, that visitors avoided the watchguard by entering through a back door, the back entrance was barricaded. Observing that new outbreaks were often

found in villages adjacent to those infected, the teams began an increasingly intensive search in a 5-mile (8-kilometre) radius around each infected village.

Information on the means by which outbreaks were actually detected are available for 3798 outbreaks from mid 1973 to mid 1975. The data for the latter half of 1974 and for the first half of 1975 show that an increasing proportion of the outbreaks was being notified by the public and a lesser proportion was detected by periodic search (Table 15.26). In the non-endemic states, notification by the public played a more important role, the proportion of outbreaks so notified increasing from 15% in the first 6 months of 1974 to 29% in the second 6 months and to 36% in 1975.

The outbreaks were detected increasingly earlier after the onset of the first case (Table 15.27), although the standard which called for 75% to be detected within 14 days was never reached. The outbreaks persisted for a shorter time (Table 15.28) but in some of them cases continued to be found more than a month after detection. With earlier detection

and better containment, the outbreaks, as might be expected, were less extensive (Table 15.29).

Assessment of the ever-more-thorough searches was modified to determine the proportion of villagers who were aware of the reward for reporting cases. It was assumed that if the existence of the reward were generally known, cases would not be hidden for long. Personnel searching for cases were instructed to convey the fact of its existence to all the villagers. Radio, posters, leaflets, rickshaws with loudspeakers and announcements at weekly local markets were also used as a means of information.

During the autumn, the number of pending outbreaks fell steadily, from 2124 at the end of September to 980 at the end of October and to 343 at the end of November (Fig. 15.24), but then the rate of decline slowed considerably. Almost as many new outbreaks were being added to the list as were

being removed. The winter season of more rapid transmission had begun. The numbers of outbreaks and cases were at a record low, but, if smallpox transmission was to be interrupted, even more rigorous methods of case detection and containment would be required.

Concern about the programme's progress suddenly turned to alarm in mid-December

### Status of the Programme in Early December 1974

Memorandum, dated 9 December 1974, from the Chief of the WHO Smallpox Eradication unit to all smallpox eradication staff:

"The autumn saga of 1974 has been marked by weeks of unexpectedly rapid decreases in the number of pending outbreaks in Asia interspersed with weeks when there has been little or no decline. At present, we seem to be again in the latter phase. Does this signal the beginning of a phase where seasonally increased rates of transmission overbalance our capability to contain the outbreaks *or* does it represent but a pause in the countdown as we regroup to redeploy forces and to tighten up containment procedures and so recommence the countdown? Unquestionably, a greater effort is required during the winter months to ensure containment of each outbreak, but the task can be accomplished.

"With search activities now reasonably well developed in most districts and with market searches and the system of rewards serving to assure discovery of outbreaks missed in search, it seems to me that now is the time to deal far more rigorously with containment measures. In many areas... staff have not dealt with containment as rigorously as is now required. This is not surprising. During the summer and early autumn months, further spread of smallpox occurred only infrequently even when containment measures were less than optimal. Inevitably, emphasis shifted to improving the search procedures, sometimes perhaps at the expense of the arduous and meticulous work required to assure 100% containment. With increased rates of transmission and more population movement, containment procedures which were effective in October are no longer so.

"At this stage, and with the comparatively few outbreaks we have, *every patient* must be subjected to 24-hour guard and, as required, food provided to the families to provide further incentive for them to stay put. If the guard is fully effective, every subsequent contact will be protected by vaccination. But *frequent* supervision by epidemiologists and senior staff is mandatory if the system is to work. Then begins the now necessary but arduous task of tracing all contacts of the patient from the time of onset of rash. This procedure is in effect in some areas but, as of the time of my visit two weeks ago, it was not in effect everywhere.

"Most important now is for each epidemiologist to consider each new outbreak as being indicative of a possible failure in the system. The question for each outbreak must be asked—'Why did this outbreak occur and what should be done to prevent a repetition of the episode?'"

1974 as major epidemics unexpectedly began in Bangladesh. Catastrophic floods, the worst in 20 years, had swept the northern districts of Bangladesh in August and September and, with the subsequent famine, tens of thousands of refugees migrated to other parts of the country. In December, smallpox began spreading rapidly and once again infected the major cities. The most heavily affected areas were along the northern Bangladeshi-Indian frontier and because of frequent travel across the border, numerous importations were to be anticipated. Of particular concern were the eastern states of India, in which the health services and the smallpox eradication programme itself were the least able to cope.

Realization that a difficult spring might lie ahead was soon followed by the ominous discovery of a cluster of outbreaks at a major

pilgrimage site of the Jain religion about 85 kilometres from Patna, the capital of Bihar (Jha & Achari, 1975). The largest outbreak was detected in December 1974 at Puri village, in which the founder of the Jains had died 2500 years earlier. Forty households were infected at the height of the pilgrimage season. Complicating the problem was resistance to vaccination, common among Jains. A special appeal was made to the principal religious leader, who agreed, reluctantly, to recommend vaccination. The entire village was quarantined by the Bihar military police. Twenty-four-hour watchguards were posted at the houses of infected persons and at key areas in the village. A community kitchen was set up to feed patients so they would not have to leave their homes for food. Pilgrims were not allowed to enter sacred pilgrimage

Fig. 15.24. Bihar State, Uttar Pradesh State, West Bengal State and the rest of India: number of pending outbreaks of smallpox at the end of each month, by month, 1974.

areas until they had been vaccinated. Although smallpox spread to 5 adjacent villages, the outbreak in Puri was finally controlled by the end of February 1975.

Elsewhere in the district, the number of outbreaks had increased from 16 to 75. Assessment revealed poorly conducted search operations and inadequate containment. Emergency measures were introduced. Whenever an outbreak was discovered, 20–25 vaccinators were dispatched to the infected village; containment vaccination was completed within 48 hours; 24-hour watchguards were posted at every infected household; and food was brought in to ensure household quarantine. Entire villages were cordoned off when necessary. Instead of a few vaccinators, dozens were assigned to each newly discovered infected village and camped there until no active case remained. In all, 102 new outbreaks were discovered in Bihar in January 1975.

#### “Operation—Smallpox Zero”, January 1975

With smallpox present in only 285 of the more than 575 000 villages of India at the end

#### Problems in Containment: a Report by a Supervisor in Bihar, May 1975

“We have the misfortune to have to inform you of a new case of smallpox in the Painathi outbreak, a 4-month-old unvaccinated male with onset of rash on 30 April. The household is only 10 metres from a household where a severe case occurred on 13 April.

“The patient and his mother left Painathi on 29 March, 2 days before containment began. The mother was enumerated but the existence of a child was not made known. They returned on 14 April but their presence was concealed by the father. Searchers went daily to each house in the village to vaccinate and to inquire about fever and rash. Dr Khan and Dr Briedert personally visited this house to find out if all the vaccinations were successful and if this woman had returned. The father of the child, however, lied to them.

“The family had been resistant and uncooperative from the start. After enumeration, vaccination was possible only when we climbed over the compound walls and forcibly inoculated each family member. After a rumour reached Dr Khan, who had been staying in the village, he had to use a trick to gain entrance to the house. He asked for a glass of water and this was denied. He knew by custom that they had a case of smallpox inside the house because nothing can be given when a case of smallpox is in the house of a member of this religious sect.

“Dr Briedert is now staying *inside* the infected house. A room-by-room search has been done and will continue daily. All visitors have been traced—all had been previously vaccinated. The mother was vaccinated on 2 May. She has a primary scar and we can only hope that she will not develop into a case. We are nonetheless isolating her and keeping her under close observation for the next 14 days.”

**Plate 15.16.** The search for smallpox cases intensified throughout 1975 as efforts were made to detect all cases of fever accompanied by rash. **A:** A village headman brings a child to smallpox eradication staff for confirmation of diagnosis. **B:** A search worker shows the WHO smallpox recognition card to children. **C:** Posters and writing on a wall advertise a reward of 100 rupees to anyone who detects a case of smallpox.

of December 1974 and with reasonable confidence that there were few undetected outbreaks, it appeared that the elimination of smallpox was at hand. However, from the experience of the past year in Bihar, it was clear that smallpox could spread rapidly in this densely populated area during the winter and early spring. Analysis of the experience in the autumn of 1974 showed that deficiencies in containment were primarily responsible for the failure to stop outbreaks. Vaccination of the population of affected villages was not as rapid as it might have been, visitors to the villages were often not vaccinated and some villages were declared free of smallpox without a thorough follow-up search. Although searches were conducted within a 5-mile (8-kilometre) radius of infected villages, some outbreaks traced to those villages were found to occur at distances of up to 16 kilometres.

At the end of December, new instructions were issued by the government entitled "Operation—Smallpox Zero". The following passages are extracts from the instructions:

"With the outbreaks so few in number, each outbreak must now be dealt with as an *absolute* emergency with maximum mobilization of staff and volunteers. As much concern should be directed to each outbreak as would be directed to control an outbreak in a non-endemic country such as in Europe. *Never* should a case occur more than 21 days after discovery of an outbreak.

"With the very small number of outbreaks present and with fully effective containment, smallpox transmission should be stopped in India in not more than 6–8 weeks. An all-India, all-out effort to achieve this objective will commence immediately and at all levels of the programme. These activities will be conducted under the code name 'Operation—Smallpox Zero' with the objective that no case of smallpox would occur after February.

#### "PROCEDURES

"1.0 A special Central command comprised of senior experienced Government and WHO staff will visit every new outbreak detected after 1 January and will revisit every outbreak in which a case is discovered more than 21 days after its discovery to ensure that every possible measure is being taken. These will supplement, not replace, other supervisory visits. To facilitate this, all new confirmed outbreaks must be reported immediately by cable to the State Programme Officer and to New Delhi. Any case occurring more than 21 days after discovery of an outbreak must similarly be reported by cable.

"2.0 Every outbreak must now be dealt with rapidly and with a massive containment effort.

Instead of three or four workers, the containment teams should consist of *15 to 20 workers or more*, headed by the District Medical Officer of Health assisted by a national or WHO epidemiologist. In urban areas, this number may be several times greater. *Vaccination in an infected village/mohalla must be essentially completed within two or at most three days.* Three or four workers must camp in the village/mohalla until all scabs have separated from the last case. Two watchguard-vaccinators must be assigned to each infected house to maintain a 12-hour watch during the day while a second pair maintains a 12-hour watch at night. Watchguards will be responsible for (1) vaccinating all persons visiting the houses of smallpox patients; (2) identifying all household contacts who leave to go to other areas; (3) maintaining isolation of smallpox cases; and (4) maintaining an hour-by-hour log book record of activities and of movement of people in and out of the households. Food, necessary medicines and housing may be supplied to the family of an infected patient on a daily basis to ensure cooperation and isolation. Smallpox containment field books with complete enumeration of the village/mohalla must be completed on each outbreak.

A typical containment team might include:

1. 4 watchguard-vaccinators for each infected house
2. 8 vaccinators of which 4 should camp each night in the village
3. 2 motivation workers (village-level workers who know the village/mohalla and are respected by the villagers)
4. 1 supervisor and 2 vaccinators to trace household contacts who have gone to other areas
5. 3 supervisors
6. 1 containment team leader.

"3.0 House-to-house search will be made in a 10-mile [16-kilometre] radius around an outbreak as well as in high-risk areas which may be outside the 10-mile radius. In the urban areas the surrounding mohallas will be searched in a similar manner. This will be followed in two weeks by a second house-to-house search within a five-mile [8-kilometre] radius to find cases which might have been in the incubation period during the first search.

"4.0 In case of a death, the vaccinator will accompany the remains to be certain that the body is properly disposed of and that all garments are buried. All attending the funeral will be vaccinated, a register of participants and their addresses will be prepared and all villages from which they came placed under surveillance.

"5.0 After 1 January, a laboratory specimen from one or two cases in each new outbreak will be collected."

It was decided that the periodic routine search programmes would consist of house-

to-house visits, whereas previously searchers had checked only a sample of houses in each village. The reward for reporting a case was increased from 50 rupees to 100 rupees. Each suspected case—i.e., one with a rash and fever—was to be recorded in a "rumour register", which was established at every primary health centre. Each patient was to be visited immediately by the local health officer and the diagnosis confirmed by an epidemiologist. If the diagnosis was uncertain, it was to be considered smallpox and watchguards were to be posted. By experience, it was found that good performance on the part of watchguards could be ensured by the simple expedient of not paying them until they were relieved of duty. If, at any time, a watchguard was not found on duty, all 4 were dismissed without pay and new watchguards were recruited. Containment vaccination was to include all persons within a 1-mile (1.6-kilometre) radius of the outbreak. In all, this meant vaccinating some 4000–5000 people in rural areas and 80 000 in urban areas (Sharma & Grasset, 1975). Search throughout an area with a 10-mile (16-

kilometre) radius, performed by locally recruited and trained staff, usually encompassed 300–600 villages. The costs of a typical containment operation in 1975 were estimated by Ježek to be about US\$2700 (Table 15.30).

Investigations into the source of the outbreak were intensively pursued by national and international epidemiologists, but now, instead of notifying neighbouring states or districts of the existence of a suspected source, they themselves proceeded to the locality. This ensured that the sources would not be missed because of difficulties with telegraphic communication or confusion due to information being received from illiterate villagers and the consequent need to spell village names phonetically.

To guard against importations from Bangladesh, special surveillance teams were assigned and special searches conducted in Muslim Bengali areas and communities in India. Special attention was given to Calcutta, in which repeated night searches were made among the 48 000 street dwellers (Spring, 1975).

Table 15.30. India: estimated manpower employed and costs of a typical containment operation, 1975

	Rupees (Rs.)
<b>1. Substantive staff</b>	
Epidemiologist, 21 days at Rs. 100 per day	2 100
Junior medical officer, 42 days at Rs. 35–50 per day	1 764
Paramedical assistant, 42 days at Rs. 15–30 per day	924
Driver, 102 days at Rs. 10–15 per day	1 224
<b>Total:</b>	<b>6 012</b>
<b>2. Additional (temporary) staff</b>	
Watchguards (assume 2 infected houses): 8 workers, 42 days at Rs. 5 per day	1 680
Search workers to search 10-mile radius (assume 500 villages), 300 search-days at Rs. 5 per day <sup>a</sup>	1 500
Search workers to do repeat search of 10-mile radius	1 500
Vaccinators to vaccinate the village population (assume 1000 population): 20 vaccinators, 5 days at Rs. 5 per day	500
Vaccinators to vaccinate population in a 1-mile radius: 20 vaccinators, 15 days at Rs. 5 per day	1 500
Supervision (at 1 supervisor to 5 worker-days)	
(a) for search of 10-mile radius, 60 supervisor-days at Rs. 10 per day	600
(b) for repeat search	600
(c) for watchguards, 1 supervisor, 42 days at Rs. 100 per day	420
(d) for vaccinators of village, 4 supervisors, 5 days at Rs. 40 per day	200

Fig. 15.25. Importations of smallpox from Bangladesh to India, 1975.

"Operation—Smallpox Zero", begun in January 1975, proved to be most successful. From November to December 1974, the number of pending outbreaks had decreased from 343 to 285 (17%); in January, to 194 (32%); and in February, to 113 (42%). As had been feared, cases were imported from Bangladesh, 30 importations being detected in West Bengal, Assam and Tripura (Fig. 15.25). Two-thirds were detected within 2 weeks of the onset of illness in the first case and only 8 additional outbreaks occurred as a result of further spread.

In all, only 308 outbreaks and 1436 cases were detected in India after 1 January 1975 (Tables 15.31 and 15.32). All were in the eastern part of India except for 10 in the far western Kutch desert of Gujarat, introduced by migrants probably infected in Bihar.

In April, 115 000 health workers undertook a week-long, house-to-house search throughout the whole of India. Independent assessment of some 5% of villages showed that 85%–96% of all villages in the various states had been searched. Among 574 517 persons interviewed, 61% knew about the reward for reporting a case and knew the amount of the reward. Only a few

<sup>a</sup> Outbreaks were reported immediately by telegraph or telephone; case reports (Table 15.31) were submitted through routine notification channels and were somewhat delayed in receipt.

outbreaks were found, all of which had resulted from importations. Smallpox had been virtually eliminated during the season of most rapid transmission. In May, the last cases and outbreaks in India were discovered.

### **The Last Case in India, May 1975**

As in many other countries, so in India the last case presented some unusual features (Ježek et al., 1978a). Saiban Bibi, a 30-year-old homeless Bangladeshi beggar, developed a rash while living on the Karimganj railway station platform in Assam, where she was begging for food. She had contracted smallpox from a patient in Sylhet District, Bangladesh. On 26 May, she went to the Civil Hospital in Karimganj, which forthwith notified the District Health Officer. Accompanied by a WHO epidemiologist and the state surveillance team, he immediately went to investigate.

The situation was alarming. For the first 4 days of illness, the patient had lived on the platform of the railway station, the gateway to the states of Assam and Tripura and the union territory of Mizoram. Between 22 and 26 May, 9 trains had stopped at the station and 4535 railway tickets had been issued to 68 different towns and cities. A programme was immediately launched to search and vaccinate in the city wards in which the railway station and the Civil Hospital were situated. Later, containment activities extended to the whole town, as well as to all villages visited by the patient since 21 May. Railway authorities were instructed to intensify surveillance activities in and around the railway stations and railway colonies. All district health authorities in Assam and neighbouring states through which the railway passed were asked to initiate intensive searches during the subsequent 14 days. Special searches were conducted in all villages within 10 miles (16 kilometres) of the district border with Bangladesh.

The patient was isolated and 4 watchguards were stationed in the isolation ward for round-the-clock duty. All patients, visitors and hospital staff, together with their relatives, were enumerated and vaccinated. The hospital was closed to visitors and the discharge of patients was stopped. One watchguard was placed at the railway station to carry out surveillance and vaccination.

Three border checkposts were established and all incoming and outgoing travellers

were checked and vaccinated. All border security forces and police outposts were alerted to look for possible cases.

Surprisingly, despite the time of year and the many persons who had been in contact with the patient, no further cases were found.

### **India Celebrates Independence Day and Freedom from Smallpox, August 1975**

Six weeks passed after the onset of illness in the last patient and the last outbreak was deleted from the list of pending outbreaks. On 1 July, the reward for reporting a case was increased to 1000 rupees (US\$125), the equivalent of 4 months' salary for an Indian labourer. This was done with some trepidation, since it was feared that unscrupulous persons might smuggle smallpox cases from Bangladesh to claim the reward. Indeed, on one occasion this did happen, but the ruse was readily detected. With a reward of this magnitude, thousands of patients with rash and fever were reported to the health authorities. Each was investigated; none proved to have smallpox.

On 15 August 1975—India's Independence Day—the government held a special celebration honouring India's freedom from smallpox, which was attended by the Director-General of WHO.

Less than 3 months had elapsed since the onset of the last case, and with smallpox still present in Bangladesh the staff were understandably apprehensive that at the last moment another focus might be found. The search continued, but an unexpected event of quite another type occurred. On the night of 15 August, the President of Bangladesh was assassinated. The government closed the airports and sealed the borders—to the extent that this was possible. It was feared that there might be yet another mass exodus of refugees.

An emergency surveillance programme was immediately put into operation, focusing on Bengali-speaking areas. Possible migration routes were identified, dozens of surveillance posts were set up at border crossings, special searches were conducted in designated high-risk areas and surveillance was intensified in Calcutta. Happily, the refugees were few and no further importations occurred.

On 16 October 1975, the last case of smallpox occurred in Bangladesh and the 2-year search began to confirm eradication throughout Asia.

### Why the Smallpox Eradication Programme Succeeded

Two papers have been published by members of the smallpox eradication staff which comment on distinctive features of the smallpox eradication programme in India that were crucial to its success. Extracts are given below:

"The strategy used and the manpower and other resources provided ... greatly contributed to the rapid success of the programme; but without the passion given to the planning and implementation of the programme by the workers, achievement would not have been possible. Jawahar Lal Nehru once said 'Planning would be meaningless unless behind the plan there was a passion—passion with a tinge of anger at delays, anger at anybody not doing his part, anger at not achieving where achievement is possible'. The national and WHO staff have fought with passion the battle against smallpox ... Hundreds of men and women—nationals and internationals—have worked up to 18 hours a day for seven days a week in the belief of an ideal which they have put above their personal happiness, their family life, their career and their health. The central level staff both of the WHO and the Government of India have spent on an average three weeks a month working in the field throughout the country to train, motivate, encourage the local staff. During the 1974 summer epidemic of smallpox in Bihar and [Uttar Pradesh], a number of WHO, central and state officers were publicly laughed at for having predicted that their states and the country would be free of smallpox in less than a year ... Men and women from different states in India and from many countries of the world put aside their racial, national, religious or social prejudices and bore together all the difficulties and hazards. Many took risks in putting aside conservative regulations, red tape and antiquated technical methodologies, when these threatened to delay their task or obstruct the path to success. The toughest of men and women on many occasions were on the verge of discouragement—from physical tiredness and mental frustration, when having to cope with hundreds of infected villages in their area of responsibility. They persevered, waiting days, weeks, sometimes months, until it was possible to send them more men, better vehicles, funds for petrol, etc. In the smallpox offices in New Delhi and also in the state, district and block headquarters, medical officers, administrators and secretarial staff worked most of the days far into the night, over the weekends and public holidays so as to make sure that those in the field received the necessary support. However, even during the most difficult stages of the programme, men and women in the field and offices discovered like Rabindra Nath Tagore that they 'acted and behold duty was joy'." (Sharma & Grasset, 1975.)

"The decentralisation of authority to implement the strategy to the district health authorities and epidemiologists who were responsible for proper utilisation of available resources resulted in the early detection and effective containment of large numbers of disease foci in the shortest possible time and the consequent quick interruption of transmission. If one considers that ... India ... [was] spending over 40 million rupees a year for the past ten years on NSEP and [that an] additional amount of about Rs. 20 million each [year was being spent by WHO] during the campaign years 1973-74 and 1974-75 ... it becomes apparent that it has not been the quantum of money spent but the manner of doing it which made all the difference between success and failure. Relative freedom at district levels to take on-the-spot decisions to spend this additional amount ... greatly contributed to the realisation of smallpox free status. Administrative and operational restraints in implementing the strategy were also minimal.

"All the national health programmes have built-in evaluation methods. The interval between occurrence of a defect/problem and its detection and the interval between the detection and correction has always been considerable ... In this smallpox campaign the continuous monitoring of the smallpox status, feedback from the field staff and the authority for taking on-the-spot decisions regarding fiscal, administrative and technical matters have narrowed down the unknown and the unsolved problems to the minimum." (Dutta et al., 1975.)

### Morbidity and Mortality Data

Information regarding the age, sex, vaccination status and survival or death of the patient was obtained for all cases in India. However, data were tabulated nationally for only a proportion of the total for the years 1974–1975 (Basu et al., 1979). These data were obtained from 4 high-incidence states and 13 low-incidence states and union territories, although most of the cases were from the former group. The age distribution of cases and case-fatality rates were similar to those observed elsewhere in the Asian sub-continent (Table 15.33).

Data are available for 23 546 of the 189 439 cases which occurred in 1974–1975. In all, 31% occurred in individuals less than 5 years of age, 40% in those aged 5–14 years, and 29% in those aged 15 years and over. The disease was equally prevalent among males and females.

A similar distribution of cases by age and sex was observed in all states with a high

incidence. Imported cases in smallpox-free states, however, occurred predominantly in males (64.6%) in the older age groups, 18.7% being in men aged 50 years and over. This was attributed to the occurrence of many cases among migrant labourers and pilgrims, a much larger proportion of whom were adult males.

Data regarding the vaccination status of 14 463 cases from the same 17 states and union territories reveal that two-thirds of the persons concerned were unvaccinated (Table 15.34). Patients were classified as “unvaccinated” if they had no vaccination scar (regardless of whether they claimed to have been vaccinated) or if they had been vaccinated during the incubation period of the disease, too late to prevent infection.

The proportion of cases among individuals with an apparent vaccination scar was markedly higher than in other countries. This is explained by the frequent occurrence of vaccination-like scars associated with the use of rotary lancets in which secondary bacterial

Total	4 767	32.9	9 696	67.0	14 463

infections occurred but vaccinia virus did not grow. Most of the cases among "vaccinated" children under 5 years of age occurred in Bihar and Madhya Pradesh, in which, as late as 1973, rotary lancets were still being used in some areas, especially the large municipalities. In Andhra Pradesh, in which the use of rotary lancets was abandoned in 1969, only 15.4% of cases occurred among those with what appeared to be a vaccination scar.

Case-fatality rates in India varied from 21% to 31% during 1950-1967 but for most years they were in the range of 25-30%. During the course of the eradication programme, the case-fatality rate dropped steadily, from 31.2% in 1967 to 16.6% in 1974 and to 12.3% in 1975 (Fig. 15.26). The decline is accounted for by an increasing completeness of the notification of cases.

Initially, most cases and deaths were reported from infectious disease hospitals, to which the more seriously ill were taken and which recorded high case-fatality rates. As time progressed, differences between case-fatality rates in the various states narrowed considerably. Moreover, a much higher proportion of cases in otherwise smallpox-free areas was found among older children and adults, who experienced a lower case-fatality rate than did young children. Data for 23 546 cases that occurred in 1974-1975 show an overall case-fatality rate of 17.4%, but among infants under 1 year of age the rate was 43.5% whereas it was only 6.5% among the 15-19-year-olds. Although wide variations in case-fatality rates were observed in different epidemics, these variations were considered to be due to differences in the age distribution of the cases, the nutritional status of patients, and the history of previous vaccination.

Fig. 15.26. Case-fatality rates for India and the states of Andhra Pradesh, Assam, Bihar, Gujarat, Haryana, Jammu and Kashmir, Karnataka, Madhya Pradesh, Maharashtra, Orissa, Punjab, Rajasthan, Tamil Nadu, Tripura, Uttar Pradesh and West Bengal, by year, 1967-1975. Each dot represents the case-fatality rate in a state in a year. For each year rates are plotted only for the states that recorded at least 100 cases that year. The bold lines denote the overall rate for India in the year shown.

## NEPAL

### Introduction

Epidemiologically, Nepal was a mountainous extension of the Indian states of Bihar and central and eastern Uttar Pradesh, but its programme differed significantly from that in India. Of the country's 10.8 million population (in 1967), 37% lived in the Terai, a northern strip of the broad Ganges river plain (see Fig. 15.1), which in Nepal was about 25–35 kilometres wide; another 53% lived in the adjacent Middle Hills area, which ranged from 30 to 50 kilometres in width. Most of Nepal's population thus lived within some 80 kilometres of the border with India and the majority were Hindu. Many had relatives in adjacent areas of India, and travellers and migrant labourers moved freely across the border. Roads were few, communications were difficult and the health services and other governmental structures were in an early phase of development.

In 1962, a WHO nurse working in Nepal assisted in the development of a pilot mass vaccination campaign in the Kathmandu valley, comprising 3 of Nepal's 75 districts with a population of 500 000. In 1968, the campaign was extended to other districts and by 1973 it included the entire country. Little was done to develop a reporting system until 1971. Data prior to this time represent only a partial enumeration of cases in the Kathmandu valley.

Strategically, the programme in Nepal was initially not of high priority in the global strategy because eradication there depended on the progress of the campaign in India, particularly in Bihar and Uttar Pradesh. Moreover, the mainly mountainous terrain, the predominantly rural population and the poor communications between villages in Nepal suggested that smallpox transmission could not be long sustained in most of the country. Since the population of the Terai was only about 4 million—the equivalent of 2 districts of India—it was expected that the interruption of transmission in that area and in the country as a whole would not constitute a major problem once smallpox had been controlled in India.

Because the health structure in Nepal was rudimentary and vaccine was available to only a small proportion of the population, additional WHO support was provided from 1968. The eradication programme was in-

tended to make vaccination more widely available initially in the most populous areas along the border with India. Three years later, a plan was implemented to extend reporting and surveillance–containment measures progressively throughout the 75 districts. Progress in achieving these goals was remarkably rapid: by 1972 each outbreak was being investigated and contained and its source identified. Continuing transmission was, in fact, largely stopped in that year. Epidemic smallpox in the neighbouring Indian states of Bihar and Uttar Pradesh, however, resulted in an additional 239 outbreaks in 1972 and 1921 cases during the period 1973–1975. Most of these outbreaks could be traced directly or indirectly to importations and although they sometimes remained undetected for many weeks and were not always well contained, smallpox did not usually spread widely. On 6 April 1975, the last known case of smallpox occurred in Nepal as a consequence of an outbreak resulting from an importation from Bihar.

### The Country: Geographical and Socio-cultural Considerations

Until 1951 Nepal, ruled by hereditary prime ministers, had been closed to the outside world, and no organized health services or educational facilities existed. When a constitutional monarchy was instituted in 1951, Nepal began the arduous task of building a transport, communication, health and educational infrastructure. Because of the mountainous nature of the country and the dearth of human and natural resources, progress was slow. Throughout the 1970s, Nepal remained one of the world's least developed countries.

Administratively, the country was divided into 14 zones, which were subdivided into 75 districts; the population of a district ranged from 7000 to 350 000, a far smaller figure than that for a district in India. The smallest administrative unit was the panchayat, of which there were some 4000.

Until the 1960s smallpox had occurred widely throughout Nepal. According to a health survey conducted in 1965–1966, 24% of people over 30 years of age in the capital city of Kathmandu bore the facial pockmarks of smallpox, as did 13% of those aged 10–29 years and 6% of children under 10 (WHO/SE/78.107, Shrestha). Variolation

was known to have been widely practised until recent years and many older persons bore the resulting scars. However, unlike the situation in Afghanistan (see Chapter 14), the practice had died out in Nepal by the time the Intensified Smallpox Eradication Programme began. No cases attributable to variolation were discovered during the course of the programme.

As in India, smallpox epidemics were reported to have occurred approximately every 5 years, the last having happened in 1958 (WHO/SE/78.107, Shrestha). However, up to 1963, there was no reporting system; indeed, until 1971 few reports were received from anywhere except the small districts comprising the Kathmandu valley, the site of the capital city. Some Nepalese, especially those living in the Terai, had been vaccinated in India, as had some living near Kathmandu or in the vicinity of the few health units that had vaccine. Otherwise, vaccination was little practised in Nepal.

Socio-economic and demographic factors played unusually important roles in the development of the programme and in the pattern of occurrence of the disease. Geographically, the country consisted of three horizontal belts (Fig. 15.27) extending across the country: the flat Terai of the Ganges river plain, with a population density ranging from 750 per square kilometre in the east to

fewer than 100 per square kilometre in the less fertile west (Fig. 15.28); the Middle Hills area, with a terrain rising as high as 3000 metres and containing a few broad populous valleys including the Kathmandu valley, which had a population density of almost 1000 per square kilometre and about 5% of the country's inhabitants; and the Himalayan mountains, comprising 30% of the land surface but containing only 5% of the population. Very few people crossed the Nepal-China border, but travel across the Nepal-India border was unimpeded and frequent.

With only 680 kilometres of paved roads and 2 short railway lines (Fig. 15.27), there was little easy communication between the different areas of Nepal, although a network of footpaths connected the 29 000 villages and market centres in which 95% of the population resided. Kathmandu (population in 1971, 150 000) and Biratnagar (population, 45 000) were the only significant urban centres. On the other hand, contacts between the Terai and Kathmandu and India were numerous and were facilitated by the few motorable roads between the two countries.

The Nepalese of the Terai are Hindu and ethnically similar to their Indian neighbours. Many resisted vaccination for religious reasons; temples to Sitalā mata, the goddess of smallpox, were to be found throughout the

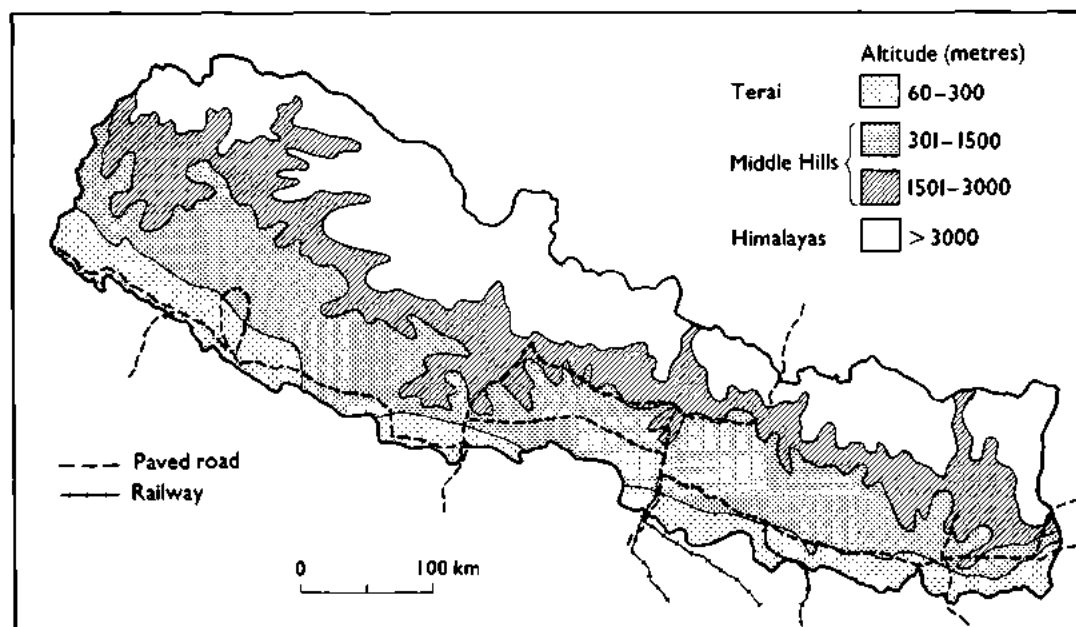

Fig. 15.27. Nepal: physical topography, showing paved roads and railways.

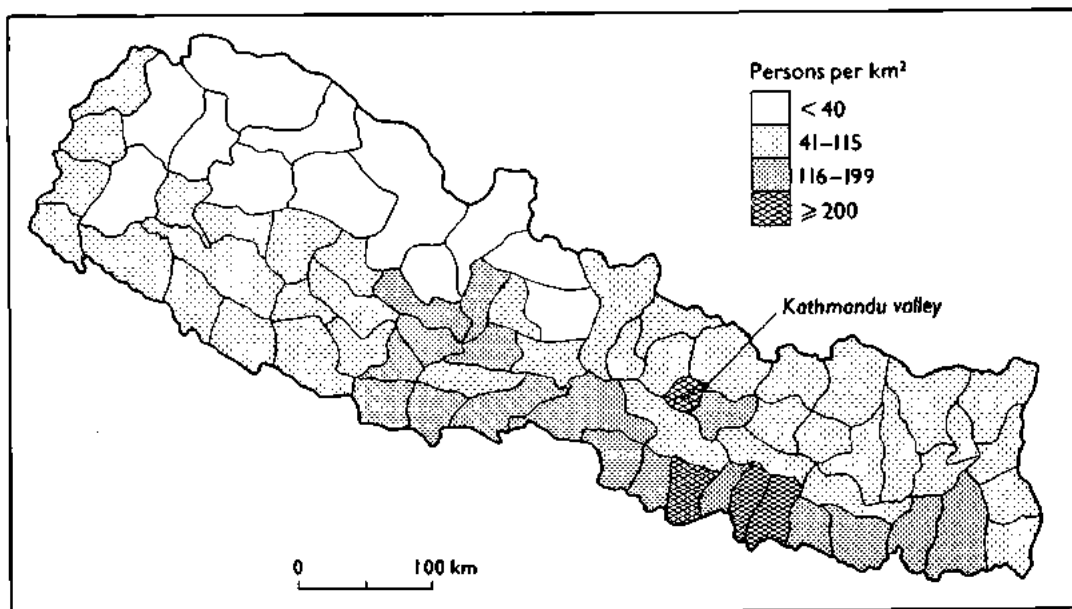

Fig. 15.28. Nepal: population density, by district.

region. The relatively rich agricultural and industrial area of the eastern Terai attracted numerous Bihari and Bengali seasonal migrants, who formed a sizeable proportion of the labour force. Travel to and from the less prosperous western Terai was limited primarily to family visits, and few travelled long distances. Those living in the Middle Hills were predominantly Hindu, but with the exception of some segments of the Newar

ethnic group in the Kathmandu valley most people readily accepted vaccination. Travel to and from the Middle Hills was less frequent than within the Terai, although many moved to the Terai and to India for the winter months. Numerous inhabitants of the Eastern Hills worked on tea estates and as forest labourers in the Indian state of Assam and those in the Western Hills travelled to western Uttar Pradesh and cities of western India for work and trade. In the sparsely populated Himalayas, villages were isolated. To reach most districts from the endemic areas of India required a trek of more than 14 days—longer than the incubation period of smallpox. Because of these factors, smallpox proved to be primarily a problem of the Terai, only 4 outbreaks ever being detected in the extensive northern mountainous areas (SME/77.1, Shrestha et al.).

Plate 15.18. At times, the roads in Nepal were almost impassable.

#### A Smallpox Control Pilot Project Begins, 1962

A smallpox control pilot project was initiated in 1962 in the 3 districts comprising the Kathmandu valley, which had a population of about 500 000 at that time (WHO/SE/69.10, Singh). With assistance provided by a WHO nurse already employed in another project in Nepal, a house-to-house mass vaccination campaign was begun, utiliz-

ing the multiple pressure method of vaccination and freeze-dried vaccine provided by WHO. As in India, all records were maintained in family registers in which the names of all residents of households were laboriously compiled, revised and updated. The programme was poorly funded, poorly supervised and poorly executed and with the additional impediment of resistance to vaccination progress was slow. A sample survey carried out late in 1964, 2½ years after the programme began, revealed that only 31% of the population had vaccination scars. In 1963, for the first time Nepal began to report cases of smallpox to WHO, but virtually all of them had occurred within the city of Kathmandu. In 1966, a WHO medical officer was assigned to assist the programme, but no effort was made to develop a national reporting system, and until 1968 the programme remained what it had been—an ineffective vaccination campaign confined to the Kathmandu valley. Repeat surveys in May 1967, conducted among various population groups in that area, showed that only 40–65% of the people examined had vaccination scars or the pockmarks of smallpox (WHO/SE/69.10, Singh).

### The Programme Extends Beyond the Kathmandu Valley, 1968

In 1967 the government and WHO agreed on a phased plan to extend the programme zone by zone throughout the country. This commenced the following year with the hope that the last of the zones would be included in the programme by 1972. Additional resources were made available by the government, and WHO provided support in the form of personnel, vehicles and equipment and also covered the cost of petrol (Table 15.35). Staff were recruited, trained and assigned to district offices to serve as "senior vaccinators". During the first 3 months of a new vaccination campaign in a district, temporary vaccinators were hired to vaccinate widely throughout the district. Subsequent vaccination and surveillance were then the responsibility of the senior vaccinator. The family registers were abandoned and multiple puncture vaccination with bifurcated needles was introduced.

The number of districts covered by the programme grew from 3 in 1967 to 15 in 1968 and to 41 by the end of 1970. The number of vaccinations performed increased

10-fold, from 201 000 in 1965–1966 to 2 196 000 in 1968–1969 and to 2 823 000 in 1970–1971 (Table 15.36).

Community leaders and such health staff as were available were contacted and requested to report cases, but the numbers of cases notified remained few: 110 cases were reported in 1967, 249 in 1968, 163 in 1969 and 76 in 1970 (Table 15.37). Although reporting was very incomplete, it is probable that the true incidence in Nepal during these years was not high because the corresponding

incidence in the neighbouring Indian states of Bihar and Uttar Pradesh was low.

### The Programme Strategy Changes, 1971

Early in 1971, a new strategy, unique to Nepal, was adopted and effectively executed by an energetic Nepalese programme director, Dr P. N. Shrestha, and an experienced WHO smallpox adviser, Dr M. Sathianathan, from Sri Lanka, assisted by 2 United States technical officers—veterans of the western Africa programme—Mr Jay Friedman and Mr David Bassett. It was decided to extend the programme as soon as possible to cover the entire country. Forty-five Nepalese district supervisors were recruited and assigned to most districts in the Terai and Middle Hills, and assistant supervisors or senior vaccinators were sent to the other 30 districts, where each worked under the direction of one of the district supervisors. A senior supervisor was responsible for managing the programme in each of Nepal's 14 zones. In 6 districts, responsibility for smallpox eradication was assigned to a newly planned integrated health services project office (Fig. 15.29).

WHO and Nepalese staff decided that the vaccination campaign would be conducted during a single month in the winter of each year, and for this purpose temporary vaccinators (1 for each panchayat, comprising about 3000 persons) were recruited and trained during a 3-day training session. Simple tally sheets replaced the more elaborate record forms. During the remaining 11 months of the year, the assigned permanent smallpox eradication staff, numbering in all

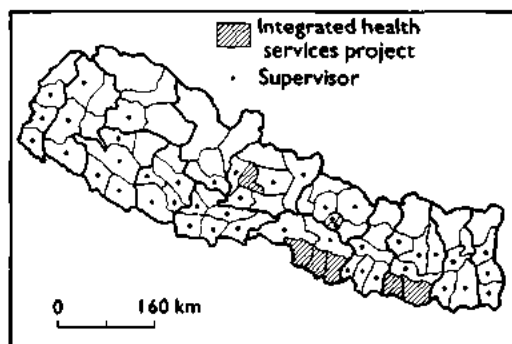

Fig. 15.29. Nepal: administrative divisions and location of district supervisors, 1971.

about 600 persons, travelled from village to village throughout the districts seeking information about smallpox from local leaders, schoolteachers and the personnel of health units. When cases were discovered, the staff were responsible for containment. Four central containment teams were formed to assist in this effort but were soon disbanded, since it proved impossible for them to reach the site of an outbreak before several days—or even weeks—had elapsed because of problems of communication and travel.

Despite the fact that mass vaccination was conducted during the course of a single month each year, the number of reported vaccinations increased to more than 6 million in 1971-1972—a number equivalent to 50% or more of the population—and continued at this level over the next 5 years. Surveys of vaccinal immunity, conducted in 1975 in many of the more accessible areas, revealed that in most of these areas more than 95% of the population bore vaccination scars.

Reporting improved as the programme extended its operations; by early 1973 weekly telegraphic reports were being received from each district regardless of whether any cases had occurred.

Because of the difficulties of travel, responsible district supervisors proved to be the vital element in the programme. They were brought to Kathmandu annually for refresher training and were visited as often as possible in the field by Nepalese and WHO staff, who, beginning in 1972, undertook to visit the site of each outbreak to assess the efficacy of the containment measures. To facilitate travel to the most remote districts, arrangements were made by WHO to permit the charter of a helicopter; it was used on perhaps a dozen occasions during the subsequent 3 years.

**Plate 15.19.** A: Purushollam N. Shrestha (b. 1939), the director of the smallpox eradication programme in Nepal from 1971. B: Jay S. Friedman (b. 1940), a WHO technical officer, being presented with a certificate of appreciation by the Prime Minister of Nepal, Tulsi Giri.

In 1972, the programme was extended to include all districts in the Terai and Middle Hills—the districts of greatest concern. Because of the isolation of the villages, most outbreaks were readily contained, and by the end of June 1972, transmission appeared to have been interrupted. During the last 6 months of the year, only 5 outbreaks, with 34 cases, were discovered (WHO/SE/74.71, Shrestha et al.); 4 resulted from importations from Uttar Pradesh and 1 from Bangladesh, whose north-western border with India was less than 50 kilometres—merely a day's journey—from Nepal.

However, as epidemic smallpox swept across Uttar Pradesh and Bihar in 1973, increasing numbers of cases began to be imported into Nepal (Fig. 15.30). In all, 43 outbreaks and 277 cases were reported that year, of which 35 outbreaks resulted from importations from India. Twenty-eight more cases occurred in these outbreaks that were not officially notified until 1974. Most of the imported cases had been infected in bordering districts of Uttar Pradesh and Bihar. The sources of the outbreaks included 12 districts in Uttar Pradesh and 9 in Bihar. One infected traveller came from the state of Maharashtra, although he was probably infected while travelling through Uttar Pradesh. All but 4 of the importations occurred in districts bordering on India.

Smallpox did not spread extensively, however. From the 35 importations, second-

dary spread to other villages occurred on only 7 occasions, one of these villages being the source of a further outbreak. The number of cases in each outbreak ranged from 1 to 38 with a mean of 8.3 cases, of which almost one-third (13 out of 43) were single-case outbreaks (Table 15.38).

In November and December 1973, the number of importations began to increase

**Fig. 15.30.** Nepal: importations of smallpox, 1973 and 1974. Each dot denotes one outbreak.

Table 15.38. Nepal: number of outbreaks of smallpox, by number of cases in each outbreak, 1973-1975

and in January 1974, 14 importations were detected, of which 8 were from Bihar and 6 from Uttar Pradesh (Fig. 15.31). The number rapidly increased during May and then abruptly diminished, which was consistent with the seasonal decline in smallpox. In all, 180 outbreaks and 1549 cases occurred, of which 115 outbreaks were due to importations. As was the case in 1973, most of them (106 out of 115) occurred in districts bordering on India, the eastern districts of the Terai being the most heavily infected. In contrast to 1973, when the sources of infection were widely dispersed geographically, 68% of all importations during 1974 came from 5 heavily infected districts in Bihar. These districts, besides being among the most heavily infected in India, experienced severe food shortages in the spring of 1974 and, in consequence, many people migrated to Nepal.

Fig. 15.31. Nepal: number of outbreaks of smallpox, by source, by month, 1973-1975.

In early 1974, WHO arranged for the prompt, reciprocal cross-notification by telegram between India and Nepal of possible sources of infection in each country. Programme staff agreed to investigate every report of this kind and to confirm whether an outbreak had been found. Nepalese staff fulfilled this responsibility well and detected a number of outbreaks not previously known. In India, especially in Bihar, the system operated far less well: with numerous outbreaks and a poorly organized health system, many reports were ignored (WHO/SE/74.71, Shrestha et al.).

The increase in the number of outbreaks in Nepal taxed the resources for surveillance and containment, and a greater number of outbreaks began to result from local spread. Nineteen out of 57 such outbreaks (167 cases) occurred between February and September following 2 importations into the Kathmandu valley. Most were in the Newar ethnic group, who had resisted vaccination for religious reasons, and among whom it was a common practice for the relatives and friends to visit those who were ill with smallpox. Detection was also difficult because families did not report cases and sometimes hid the patients from health officials. Smallpox could therefore spread widely and containment was difficult.

A second problem area was in the western Terai, in which another ethnic group who also resisted vaccination had the custom of granting any wish to a child with smallpox in the belief that the child was possessed by the goddess of smallpox, Sitalā mata. The child's wish was frequently to be taken to see relatives or friends in other villages. In this area, smallpox spread unusually rapidly among groups of villages (SME/77.1, Shrestha et al.).

A third area which proved difficult was a south-eastern district, Morang, which experienced 29 importations in 1974 and 1 in 1975. It was the centre of jute production in the eastern Terai and contained the industrial town of Biratnagar. Numerous migrant labourers from India were attracted to the area and, in the autumn of 1974, because of food shortages in Bihar, many beggars from India arrived there. Quite a few of the migrant labourers and most of the beggars belonged to a tribal group which worshipped Sitalā mata and resisted vaccination (SME/77.1, Shrestha et al.). The last chains of transmission began in December 1974 and

WHO: P. BOUCAS

**Plate 15.20.** Tibetan pilgrims being vaccinated in front of a Buddhist temple at Bodnath in the Kathmandu valley, Nepal.

January 1975, when 21 cases, primarily among beggars, occurred in a large market area, and from there smallpox spread to 6 nearby villages. More vigorous containment efforts were required; thus, in January, watchguards were posted at each infected house, as was done in India. In addition, systematic search and vaccination programmes were conducted over wide areas encircling the site of an outbreak. The system had been in use in many states of India for more than a year but in Nepal, in which the population was sparse, the containment of outbreaks had been less of a problem and, with fewer personnel, it had been impossible up to this time to adopt the Indian methods of containment. With the numbers of outbreaks diminishing both in India and in Nepal, a more elaborate scheme was possible. Resistance to vaccination was usually overcome with verbal persuasion although, on occasion, police accompanied the vaccinators to lend their authority. The number of outbreaks declined rapidly, and on 6 April 1975 the last cases occurred in Nepal.

Data regarding the age distribution of cases are available for 1286 of the 1921 cases which occurred in the period 1973-1975

(Table 15.39). Smallpox in Nepal occurred more frequently among older children and adults than in India. Less than one-third of all cases were in children under the age of 5 years and 29% were in persons over 15 years of age. The fact that more cases tended to occur in the older age groups in Nepal than in India probably reflected lower levels of vaccinal immunity throughout the population as well as a lower level of naturally acquired immunity due to the relative isolation of villages. Although villages in Afghanistan were comparable in their degree of isolation, vario-

lation had been extensively practised there and many persons were immune as a result. In Nepal, however, the procedure had been largely discarded in recent decades.

Only 40 out of 1915 patients (2.1%) for whom data are available had been vaccinated before exposure—a far lower proportion than that reported from India. Several factors could account for this. In India, in which rotary lancets had long been in use, many apparent vaccination scars resulted from sepsis rather than successful vaccination. In Nepal, few had been vaccinated with the

rotary lancet. Moreover, in the vast majority of instances the vaccination had been performed after 1967 so that vaccinal immunity was likely to be at a higher level.

The case-fatality rate was 21.5% (411 deaths among 1915 patients), a figure consistent with observations elsewhere in the Asian subcontinent.

At the time that the last case occurred, a reward of 100 rupees (US\$9.50) was being offered to anyone reporting a case, and later this sum was increased to 1000 rupees. After 6 April 1975, however, no reported case was

confirmed and no further cases were detected in subsequent laborious house-to-house searches.

### Cost of the Programme

The total outlay on smallpox eradication by the government of Nepal and by WHO during 1962–1976 amounted to US\$2 378 982, or just over US\$0.15 per head of population. For the period 1972–1976, approximately 2% of the Ministry's health budget was spent on the programme. The expenditure, however, was low compared with the cost of other programmes such as that for malaria control, on which, in the year 1976–1977 alone, Nepal spent more than US\$4.5 million (SME/77.1, Shrestha et al.).

### SIKKIM AND BHUTAN

East of Nepal in the Himalayan mountains lay 2 small sparsely settled political entities—Bhutan and Sikkim (Fig. 15.32). Bhutan, an independent monarchy, had an estimated population (in 1967) of 987 000, which was concentrated in the central and southern parts of the country and had contact through trade and travel with the inhabitants of Assam, West Bengal and Bihar in India. Between Nepal and Bhutan was the even smaller and less populous Indian protectorate of Sikkim (population in 1967, 196 000), which in 1975 became a state of India. Both areas shared a northern border with China, but few travellers crossed it.

Sikkim and Bhutan were both at risk of smallpox imported from India, although in neither area had it seemed likely that smallpox transmission could be long sustained among the population of the scattered mountain villages. Thus, until smallpox transmission was interrupted in India and Bangladesh, little support was provided by WHO to either Sikkim or Bhutan and, in fact, information about the smallpox situation in both areas was scanty until late in the Intensified Programme. With the interruption of smallpox in India, attention was directed to these and other more remote areas of the subcontinent to ascertain something of the history of smallpox and smallpox control in recent years and to confirm that transmission was not continuing.

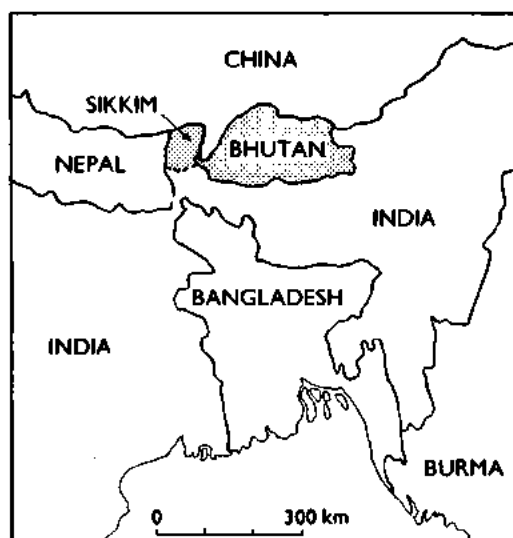

Fig. 15.32. Bhutan and Sikkim and adjacent countries.

### Sikkim

Cases of smallpox had been officially reported in Sikkim since 1954. In 1966–1967, 78 cases in all were recorded at a time of high incidence in northern India. After this, no further cases were reported until 1973, when an outbreak of 34 cases occurred in Gangtok, the capital, the first case having been infected in Darjeeling, West Bengal. A second outbreak, of 11 cases, occurred that year in 2 villages along Sikkim's southern border, the source of infection again being West Bengal. No further cases were detected subsequently. Although reporting was undoubtedly very incomplete, the sporadic occurrence of smallpox was characteristic of an area in which importations were rare, and when they did occur, the disease did not spread easily.

Vaccination had been offered at the 4 district hospitals and 27 dispensaries, and the

Table 15.40. Sikkim and Bhutan: number of reported vaccinations, 1967–1975

Year	Sikkim	Bhutan
1967	114 575	35 944
1968	57 879	18 117
1969	71 812	9 029
1970	49 095	8 114
1971	36 832	43 052
1972	39 652	18 518
1973	45 801	57 375
1974	36 331	53 822
1975	28 846	25 599

number of vaccinations relative to population, at least from 1967, was quite substantial (Table 15.40). That vaccinal immunity was comparatively high was confirmed during a vaccination scar survey in November 1975, which revealed that 79% of the population had scars and only 42 of 1495 persons (2.8%) had the facial pockmarks characteristic of smallpox (Basu et al., 1979).

### Bhutan

Information about Bhutan is less complete than for Sikkim. Until 1961 no health department had been established in the country. In 1964, the government created 19 posts for vaccinators, and increased the number to 25 in 1966, when a mass vaccination campaign was begun following an outbreak of 74 cases of smallpox in 1965-1966 in the capital city of Thimbu. The outbreak had begun among Indian and Nepalese workers employed in a road-building project and then spread to the local population. The number of vaccinations reported to have been performed between 1967 and 1975, however, was small in relation to the population of 987 000 (1967 estimate).

After the 1965-1966 outbreak, only 4 further outbreaks were reported. In 1967, 2 outbreaks originating in Assam caused 14 cases. The third outbreak, of 6 cases, occurred in April 1973 in a village near the south-western border with India, the initial case having been infected on a tea estate in West Bengal. The fourth outbreak, near the same border area, occurred in February 1974 and consisted of 3 cases, of which the first had been infected in Assam. Surveys conducted in 1976 to detect individuals with facial pockmarks, as well as interviews with village officials, indicate that other, unreported, outbreaks had occurred although none had produced more than a few cases. This was attributed in part to the fact that the villages

were scattered and isolated, and in part to the sensible traditional practice of isolating the patient and his family at the onset of illness in a place some distance away from the village. In these circumstances, the spread of smallpox was difficult.

Sample surveys conducted in Bhutan in the autumn of 1976 confirmed that vaccinal immunity among children was generally low, especially in the central and northern parts of the country (Table 15.41).

Facial pockmarks indicative of past smallpox were not seen in anyone under 15 years of age in central and northern Bhutan but were observed in 11 children in southern Bhutan. In northern Bhutan, where adults also were examined, only 10 out of 244 persons (4%) over 15 years of age had the facial scars characteristic of smallpox, the youngest being in his late twenties.

In addition to the 11 children with facial pockmarks detected in the village surveys of southern Bhutan, 3 others were discovered during surveys of schools in this area. Nine of the 14 had experienced illness in 1967 or later, and in each instance efforts were made to identify the source of infection; all were traced to India. One had contracted smallpox while living in Allahabad, Uttar Pradesh, before moving to Bhutan. The other 8 became ill in outbreaks resulting from importations (Table 15.42).

### Summary

The surveys confirmed the belief that the continuing transmission of smallpox in these sparsely populated, isolated countries had not occurred recently—even in Bhutan, in which vaccinal immunity was low. The tradition of isolating the patient and his family, observed in Bhutan, undoubtedly contributed significantly to stopping transmission. This custom, interestingly, was current throughout most mountainous areas of Asia, but was much less frequently practised in the lowlands.

Table 15.41. Bhutan: survey of vaccinal immunity and facial pockmarks in children, by age group, 1976

## CONCLUSIONS

From 1961, when India first decided to embark on a national eradication programme, to 1975, when the last case was detected, the programme gradually improved—in the quality of vaccine employed, in the vaccination technique used, in the reporting system, in the extent and intensity of surveillance and containment and, most important, in the quality of supervision. To undertake a national programme in a country so vast, with a population so large and a bureaucracy so complex, was inevitably difficult. To modify and redirect such a programme proved no less difficult. The dimensions of the effort, which involved at least the part-time participation of more than 150 000 field staff and contact with more than 550 million persons, are hard to grasp or communicate.

India's population, in 1967, constituted almost half of the total number of inhabitants of the endemic countries and, indeed, 15% of the world's entire population. The central direction of the enormous national campaign then in progress rested with only 1 medical officer and a small staff of clerks. In the states, of which 7 each had a population of more than 40 million, direction was generally entrusted to a single medical officer, for whom, in most instances, smallpox eradication was but a part-time responsibility. Working in the cities, towns and villages, however, were tens of thousands of vaccinators, basic health workers, family planning and malaria eradication programme staff and many other categories of health worker. Many were responsible, experienced individuals, conscientious about their jobs and willing to work, but they were seldom provided with much in the way of support or stimulus or the necessary supplies to carry out their assigned tasks. New directions or new policies were more often than not impersonally communicated by official memoranda which frequently demanded the impossible

for example: "All persons in the state will be vaccinated cent per cent [100%] during the next 12 months." Vehicles stood idle and refrigerators remained inoperative for want of petrol or a few spare parts because the monetary resources provided had proved inadequate and/or fiscal procedures were so cumbersome as to prevent the disbursement of the funds. Vaccine deliveries were erratic and numerous batches were unfit for use because of the lack of refrigerated storage.

In the opinion of many, the solution to the disappointing level of productivity throughout the health sector was to eliminate special programmes such as that for smallpox eradication and to integrate all programmes into a unified primary health care programme in which each health worker would assume a multiplicity of responsibilities as a "basic health worker". This was the panacea which had been repeatedly proposed by both Indian and WHO expert groups since the 1950s. It was the course of action recommended in 1966 as India's intensive national vaccination campaign drew to a close, with smallpox almost as widespread as it was before the campaign had begun. In a number of states such integrated programmes were started in the mid- and late 1960s but the productivity of the workers was, if anything, even lower than it had been before.

Given the difficult problems and the paucity of senior leaders, the achievements of the smallpox eradication programme between 1967 and 1973 were remarkable. By the summer of 1973, smallpox transmission had been virtually interrupted in the southern states and was declining in the western states. It seemed that a comparatively modest investment in time by senior epidemiologists to help to develop surveillance and containment activities in the other states should rapidly succeed in interrupting transmission throughout India. The deplorable condition of the health services in some of these states, especially Bihar, Assam and Uttar Pradesh, was not then comprehended, nor were the coming disastrous epidemics anticipated. However, the administrative changes which were made in the summer of 1973 had profound consequences in that they permitted the vast resources of health manpower in India to be utilized effectively and gave scope to the imagination and problem-solving abilities both of senior staff and of field workers. With the active support of the Minister of Health and Family Planning and

an adequate complement of senior Indian and WHO staff to travel to the field to explore alternative solutions to problems, to instruct, to assess and to measure results, field staff took an increasing interest in the programme. Knowing what should be done, they themselves sought new solutions. The onerous fiscal constraints were ultimately resolved through the use of the flexible imprest accounts provided by WHO. With the most senior Indian staff, initially Dr Diesh and later Dr Sharma, not only travelling to state capitals but also visiting field staff in districts and villages, the example was set for otherwise desk-bound lower-level supervisory staff to do likewise. By doing so, they motivated and inspired staff at all levels.

The strategy adopted for the programme also played an important role, the country being divided into 3 different areas, with the objective of preventing smallpox from re-establishing itself in smallpox-free states, of eliminating the few remaining foci in states with a low incidence, and of conducting a major offensive in the 4 states with the highest endemicity. Each of the states thus had specific goals and programmes appropriate to those goals. Measurable indices of progress in achieving eradication were important. These were identified first in terms of the numbers of cases of smallpox occurring each week and then in terms of the numbers of outbreaks in which a case had occurred during the preceding 4 weeks. In the last year of the programme, other standards were formulated to measure the quality of surveillance, of containment and of outbreak investigation. With specified and achievable objectives, all personnel could assess progress in their own area, be it a primary health care centre, a district or a state. Monthly meetings and regular surveillance reports served as refresher training, permitting new approaches to be introduced and serving as a stimulus to all concerned.

The problems that emerged after the intensive campaign was launched in the summer of 1973 were far greater than anyone had expected, but the conviction of the senior leadership and the programme's momentum were sustained in the face of often hostile criticism by some senior Indian and WHO officials, natural calamities of flood and famine, civil disorder and strikes, and the inevitable bureaucratic inertia. The programme improved so rapidly that the

transmission of smallpox was interrupted in India less than 20 months after the first search had begun. Because of the quality of the programme and the confidence achieved through assessment of its merits, it was possible only 3 months after the occurrence of the last case to celebrate India's freedom from smallpox on India's Independence Day in August 1975. In no other country up to that time had it been possible to feel so confident so soon. However, over the next 2 years, the programme staff conducted the most elaborate and extensive search programme of any in Asia to confirm for themselves and—just as important—to convince an incredulous world community that India was truly free of smallpox.

What many failed to appreciate was that the achievement was not the product of a special army dedicated to smallpox eradication, but one in which existing health staff of all types participated actively in managing and executing a programme with measurable objectives. When eradication was certified in 1977, only a handful of long-term smallpox vaccinators and a few senior staff remained to be reassigned to other programmes.

As had been expected, smallpox in Nepal, Bhutan and Sikkim reflected the experience in the neighbouring densely populated Indian states. In Bhutan and Sikkim, the only special activities undertaken, aside from routine vaccination programmes, were those concerned with certifying the absence of smallpox. In Nepal, far more populous and epidemiologically more closely related to India, a special programme was required.

The programme of vaccination and later of surveillance and containment in Nepal represented its first national health programme, and one which extended to all parts of this mountainous rugged country. Since travel throughout much of Nepal was of necessity by footpath, and health facilities were non-existent in many parts of the country, district smallpox supervisors played a vital role. With encouragement from national staff and repeated refresher training, most of these local workers responded well to their responsibilities. The first national disease reporting system was established, and vaccination—all but unknown in most of the country in 1967—reached more than 90% of the population within a period of little more than 5 years. It was an impressive achievement, especially in view of the fact that the ratio of programme staff to population was at

best 1 to 20 000. Nepal's successes were different from India's but no less remarkable.

The programme in India was slow to gain momentum and undoubtedly eradication might have been attained far sooner if an adequate complement of well-motivated senior supervisors had been provided at an

earlier stage. In all probability, the greatest catastrophe of the Intensified Programme would have been averted—namely, the 1971 epidemic in the Calcutta Salt Lake Refugee Camp, which led to the reintroduction of smallpox into Bangladesh and to tens of thousands of deaths.

### INTRODUCTION

The last case of smallpox in Asia and the last case of variola major, the more severe form of the disease, occurred in Bangladesh (Fig. 16.1) on 16 October 1975. It might not seem surprising that Bangladesh was the last Asian country to eliminate smallpox. Of all the countries of the world, it was one of the poorest and most densely populated. However, Bangladesh (East Pakistan until December 1971) had already succeeded once in interrupting transmission 5 years earlier, in August 1970. The achievement had been remarkable and unexpected, occurring just 8 months after limited resources had been diverted from an extensive mass vaccination campaign to a simple surveillance and containment programme. Most observers believed that other undetected foci would

become apparent during the subsequent dry season, from October 1970 to the end of March 1971, when more rapid transmission occurred. However, 6 months went by without further cases being found. Suddenly, in March 1971, a tragic and violent civil war broke out, 10 million refugees fled to India, and health programmes and organized surveillance activities virtually ceased. However, up to the end of December 1971, no smallpox patients were admitted to the infectious disease hospitals, no cases were reported by health staff and none were detected among the continuing flood of refugees entering India.

Many of the refugees who fled to India were housed in special camps, hurriedly set up in areas near the border. They were supposed to have been vaccinated on arrival, but in several camps, including the largest, near

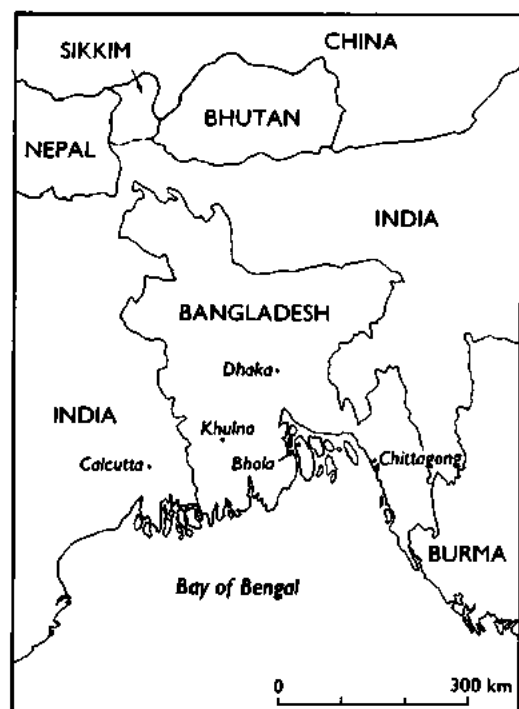

Fig. 16.1. Bangladesh and surrounding countries.

Calcutta, few were, in fact, vaccinated. Smallpox broke out in November 1971 and spread rapidly. Because cases were incorrectly diagnosed, nothing was done to contain the epidemic until late in January 1972.

Meanwhile, on 16 December 1971, Bangladesh became an independent state, and every day thereafter thousands of refugees, many of whom were infected with smallpox, began to return home. This mass migration took place at the beginning of the season of highest transmission. The health service, devastated by civil war, could not cope with the situation; epidemic smallpox swept through temporary refugee camps, cities and rural areas.

The eradication programme was reconstituted and strengthened, but, despite far more intensive efforts than had been made in 1970, transmission persisted year after year between 1971 and 1975, as one disaster followed another. At different times, famines, floods, civil disorder and the forcible displacement of urban slum dwellers caused hundreds of thousands of people to flee their homes. The national health services were reorganized at a critical time, in 1973, seriously hampering field activities; and national leaders periodically redirected the smallpox era-

dication programme towards mass vaccination campaigns.

In the spring of 1975, a greatly strengthened although frustrated and demoralized staff made one more concerted effort to stop transmission and ultimately succeeded in October 1975, when the last case occurred.

During its final year the eradication programme in Bangladesh utilized and further developed methods that had been elaborated over the preceding 8 years of the Intensified Smallpox Eradication Programme and employed experienced personnel from many other countries. The national programme is thus of special interest. However, if the refugees in the camps in 1971—amounting to perhaps 300 000 persons—had been vaccinated, this chapter would have been very brief; 223 000 fewer cases of smallpox would have occurred and more than 40 000 deaths would have been averted.

Of the national smallpox eradication programmes, that in Bangladesh is one of the better documented; much of the material for this chapter is drawn from a book by Joarder et al. (1980), *The Eradication of Smallpox from Bangladesh*. The book also describes the eradi-

cation staff's experience in the practical application of techniques for surveillance and assessment in other health programmes.

## BACKGROUND

The richly fertile country of Bangladesh lies at the delta of three of Asia's great rivers—the Ganges, the Brahmaputra and the Meghna. More than nine-tenths of the country is less than 15 metres above sea level, and as much as one-third of the agricultural land is flooded during the June–September monsoon. In 1967, Bangladesh had a population of some 62 million, one of the fastest growing and with the highest density of any major country (428 persons per square kilometre). The central and southern parts of the country were the most densely settled (Fig. 16.2). Even in areas in which vaccinal immunity was comparatively high, the number of susceptible individuals per square kilometre was greater than in most endemic countries.

There was considerable population movement throughout the country. Nearly 95% of the people lived in rural areas, but 30% were landless and even those with some land of their own often sought part-time work elsewhere as tenant farmers or labourers. At planting and harvest times, hundreds of thousands of people travelled up to 200 kilometres in search of work. Although there were only 3 cities in 1974 with populations of more than 300 000—Dhaka (1.8 million), Chittagong (970 000) and Khulna (480 000)—all cities and towns had large unenumerated transient populations entering and leaving each day. A study in Dhaka in 1976, for example, showed that more than 110 000 persons passed daily through its main

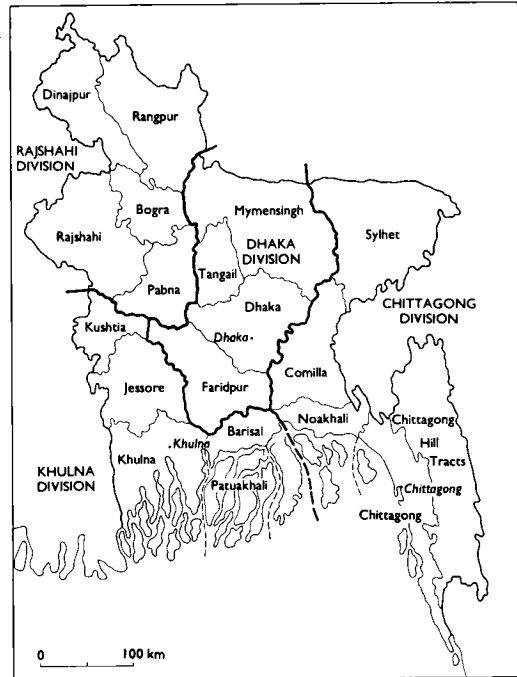

Fig. 16.3. Bangladesh: divisions and districts as of 1972.

points of entry. However extensive the movement of people, village and family ties remained especially important in this traditional Muslim society, so that those who fell ill frequently travelled long distances to be cared for in their home villages by their families. In this setting, the transmission of smallpox from urban to rural areas was rapid and widespread.

Undernutrition and malnutrition were common even when harvests were good. In 1962–1964, it was estimated that the residents of only 54% of rural households were adequately fed, and by 1975–1976 this proportion had decreased to 41%. Because of the precarious nutritional situation, even a small decrease in food supplies had a disproportionately heavy impact, causing hundreds of thousands of people to migrate from one area to another, many to the cities. At such times, smallpox spread with facility.

Travel by land was time-consuming and difficult, making it hard to supervise the programme effectively and to transport supplies to smallpox eradication staff in the field. A network of 4000 kilometres of all-weather roads radiated from Dhaka to district towns but major ferry crossings were encountered frequently and roads were often damaged or

WHO / L. DALE

**Plate 16.1.** River-boats provided transportation for many travellers in Bangladesh and, with the large crowds, smallpox spread rapidly and widely across the country.

washed out by monsoon rains. Hundreds of thousands of river-boats provided transport for many travellers; although they were slow, they were inexpensive and permitted extensive population movement, especially during the monsoon season.

The various administrative units, to which reference is made later, as well as their average area and population size, are enumerated in Table 16.1. Division and district boundaries are shown in Fig. 16.3.

Each village was composed of a number of *baris*. A *bari* usually corresponded to a household, but it also referred to a compound occupied by an extended family and sometimes included the houses of servants and other employees in the wealthier families.

In each district and subdivision, civil surgeons were responsible for all curative and preventive services except for the malaria eradication programme, which operated as an autonomous activity until late 1973. One or two medical officers were usually assigned to each *thana*, the basic administrative unit, but preventive measures were the responsibility of a sanitary inspector, who supervised some 5–10 government health assistants. Each government health assistant—a category of staff usually recruited locally—was in charge

of a union. Many of the government health assistants had no more than an elementary-school education; none were well paid or adequately supervised. Until late 1973, the malaria eradication programme, one of the best of its kind in Asia, had an independent but roughly parallel structure. Its staff, however, was of a generally better quality, received higher pay and was far more reliably supervised.

### SMALLPOX AND ITS CONTROL BEFORE 1968

As elsewhere in the Indian subcontinent, only the variola major variety of smallpox was known to have occurred, and this fertile, heavily populated delta area may well have been one of the earliest endemic areas in Asia. Until late in the 19th century, protection was afforded primarily by variolation, performed by indigenous practitioners. Vaccination, with liquid vaccine produced in Calcutta, was introduced in 1860 in areas near Calcutta and in certain of the district towns of what is now Bangladesh. In 1874, the authorities decided that variolation should be abolished and they encouraged the variolators to replace variola

Fig. 16.4. Bangladesh: number of reported cases of smallpox, by year, 1950–1977.

virus by vaccinia virus. By the turn of the century, as vaccination became more widely available, variolation ceased altogether. In 1947, the production of liquid vaccine began in Dhaka, and up to 1961, vaccination was performed throughout the country by government-paid vaccinators supervised by health inspectors in each *thana*. The extent of vaccinia immunity is unknown but with only the thermolabile vaccine available in this subtropical area, many vaccinations were probably unsuccessful.

Smallpox was known in Bangladesh as *boshonto*, the Bengali word for spring, the season of highest incidence of the disease. As in India, major epidemics were recorded every 4–7 years. After 1947, the year in which Pakistan became independent, major epidemics were recorded in 1951 and 1958 (Fig. 16.4), the latter being so extensive that assistance for its control was sought from other countries. In all, 79 060 cases with 58 891 deaths were reported that year, a figure which, because of poor reporting, was undoubtedly one-tenth or less of the actual total. One of the groups providing assistance was a team from the United States Communicable Disease Center (later, the Centers for Disease Control), Atlanta. This team estimated that 60–70% of the people had vaccination scars but could find no correlation between the level of vaccinia immunity and the intensity of the epidemic in different

areas. The team members were impressed by the size of the epidemic and the density of the population and suggested that “the number per square mile of unvaccinated persons would be a better index of the susceptibility ... than the index that is ordinarily used, the proportion of the population that has been vaccinated” (Usher, 1960). They concluded that the “feasibility [of global eradication] under presently existing circumstances is dependent on the likelihood of success in countries where eradication is likely to be most difficult to accomplish and the obstacles greatest. One of these countries is Pakistan ...” (Usher, 1960). As an outcome of the epidemic, it was decided to develop a laboratory in Dhaka capable of producing freeze-dried vaccine, but substantial quantities of such vaccine did not become available until 1966.

Resolution WHA12.54, adopted by the Twelfth World Health Assembly in 1959, called on all countries to join in a mass vaccination programme with the aim of eradicating smallpox. This initiative was enthusiastically supported by the Pakistani government and a campaign commenced in East Pakistan in 1961. The intention was to vaccinate the entire population within two or three years.

During the 3-year period 1961–1963, 72 million vaccinations were reported to have been performed and, during the succeeding 3

years, 68 million more—in all, more than twice the population of the country (Table 16.2). From field observations in 1967 and 1968, it was apparent that the reported number of vaccinations was greater than the number actually performed and, as was the case elsewhere in Pakistan and in India, the most accessible persons, such as schoolchildren, were vaccinated repeatedly while others were not vaccinated at all. Nevertheless, vaccinal immunity in the population undoubtedly reached higher levels than ever before. Only 69 cases of smallpox were reported in 1964, and 316 in 1965. In 1966, the number of cases again increased, reaching 3207 that year and 6648 in 1967.

During the summer of 1967, epidemiologists who had conducted studies of smallpox in West Pakistan (see Chapter 14) decided to undertake similar studies in rural East Pakistan. A combined team from the Pakistan Medical Research Centre in Lahore, the Cholera Research Laboratory in Dhaka, and WHO studied the epidemiology of smallpox in an area in which cholera vaccine trials were then in progress. These investigations, along with those in West Pakistan, were the most comprehensive epidemiological studies conducted during the entire global eradication programme and provide an interesting overview of the smallpox situation at that time in one subdivision of the country (Thomas et al., 1971a,b).

The area studied was Matlab Thana, Comilla District, 65 kilometres from Dhaka; it

included 132 small rural villages (population, 113 000) scattered over approximately 200 square kilometres. Vaccinators had been employed in the district since 1930, travelling from village to village to vaccinate newborn children and revaccinate others, using the rotary lancet and liquid vaccine. Comilla District had served as a pilot programme area for the 1961–1963 mass vaccination campaign and, for this operation, additional vaccinators had been employed. Therefore, as the investigators noted, vaccinal immunity among individuals over 5 years of age may have been better than in other parts of East Pakistan.

In May 1967, experienced interviewers, employed in the cholera vaccine trials, visited each house throughout the area to assess vaccinal immunity; in all, 103 539 persons were examined. In July, each house was again visited in an effort to identify, by means of an interview, all cases which had occurred between 1 July 1966 and 30 June 1967.

Of the people examined, 80.8% had a vaccination scar, the largest proportion of the unvaccinated being among children under 5 years of age (Table 16.3). This age group should have been vaccinated during the "maintenance vaccination" campaign, but, as is apparent, that programme was far from satisfactory.

Thirty different outbreaks, occurring in 27 villages, with a total of 119 cases, were identified. Of these, only 5 outbreaks and 13

<sup>a</sup> Population estimates from United Nations (1985).

cases had been officially reported but, as in West Pakistan, the reported outbreaks included 5 of the 6 largest, in which 54 cases had occurred. In 7 outbreaks, special vaccination control campaigns had been conducted by government vaccinators but with little apparent effect.

The age distribution and case-fatality rates (Table 16.4) were similar to those observed elsewhere in Pakistan and in India. Thirty-four (29%) of the cases were in children under 5 years of age, 55 (46%) in individuals aged 5–19 years and 30 (25%) in those aged 20 years and over. Thirty-four of 111 persons (31%) of known vaccination status had previously been vaccinated, all except 6 of them being 10 years of age and older. With data available regarding the vaccination status of the population as a whole, it was possible to calculate vaccine-efficacy ratios by age based on vaccination at some time in the past (WHO/SE/69.11, Thomas et al.). The ratios showed 94–96% protection for those aged up to 14 years; 89% for those aged 15–24 years; and 74% for those aged 25 years and more. The ratios were remarkably high, although not so great as those found in South America, in which only the mild variola minor variety of smallpox was present.

The epidemiological pattern of spread was of special interest. Thirteen of the 30 outbreaks consisted of only a single case, and in 9 others the disease was not transmitted beyond the initially infected *bari*. Moreover, 24 of the outbreaks terminated after less than 2 generations of spread. Despite the density of population and a lower level of vaccinal immunity, smallpox tended to spread less rapidly and to remain more localized than in West Pakistan. The sources of 22 outbreaks

were identified. All but 1 of the sources were outside the study area and 15 of the 22 originated in cities of 100 000 inhabitants or more, in which only 5% of the population of the province resided. In this study population, continuing transmission of smallpox from village to village had not occurred and, in fact, no cases whatever were detected whose onset took place between September and December 1966.

The investigators concluded that it was even more important in East than in West Pakistan to eliminate smallpox from urban areas, an objective which, if achieved, would prevent a high proportion of rural cases. Moreover, it appeared that most outbreaks in rural areas might be contained simply by vaccinating the inhabitants of the affected and neighbouring *baris* rather than the population of the entire village. Noting the high vaccine-efficacy ratios, the investigators recommended that a continuing programme of maintenance vaccination should concentrate on vaccinating those who had never been previously vaccinated, especially children aged 5–14 years not attending school and landless labourers working in urban areas—identified as the two groups most likely to transmit smallpox from place to place.

For a settled population and one which was as well vaccinated as that of Matlab Thana, the recommendations were sound and in 1970 the programme would substantiate their validity. However, when mass migrations of refugees took place, as happened repeatedly after the country became independent, and when smallpox outbreaks occurred in areas in which vaccinal immunity was low, more extensive containment measures were found to be required.

### THE WHO-SUPPORTED ERADICATION PROGRAMME BEGINS, 1968

In July 1967, Dr Ehsan Shafa, the regional smallpox adviser from the WHO Regional Office for the Eastern Mediterranean, and Arita held meetings with government officials in Islamabad, the national capital, and Dhaka, the capital of East Pakistan, and developed a draft plan of operations. The government agreed to the plan in principle and submitted a letter to the WHO Regional Office requesting assistance. This letter permitted funds to be obligated and supplies to be procured well before a more formal agreement was signed by WHO and the government, inevitably a long process. (The agreement was not, in fact, signed until 26 April 1968.)

The principal component of the plan was a mass vaccination campaign, as in West Pakistan. It was thought that a well-organized campaign and concurrent assessment of the results, coupled with the use of freeze-dried vaccine and bifurcated needles, would achieve a higher level of vaccinal immunity than had previous campaigns. Provision was made for surveillance teams in areas in which mass vaccination campaigns were in progress, but the concept of a national surveillance programme did not take shape until 1969.

Although the findings and recommendations of the research team were available to national and WHO staff by early 1968, they were almost wholly ignored in the implementation of the national programme.

The plan called for a special full-time staff comprising a headquarters office with physicians and supporting staff, 2 medical officers in each district, a medical officer in each subdivision and vaccination teams totalling some 1500 persons. The programme was to begin in 6 of the 17 districts and was to be completed in these districts during the first year of operation. Vaccination campaigns would subsequently be conducted in the remaining districts during the second and third years. The vaccination teams would move progressively from one union to the next and assessment teams would check the coverage. It was expected that sufficient freeze-dried vaccine could be produced by the Dhaka laboratory for both East and West Pakistan. For the first year, WHO provided the following items: 10 motor vehicles, 130 motor cycles, 5 boats and 1500 bicycles, in addition to other supplies. Up to the end of 1971, WHO support to the programme ranged between US\$ 67 000 and US\$ 201 000 per annum (Table 16.5). It did not increase significantly until 1974.

A WHO epidemiologist, Dr Karel Markvart, arrived in January 1968 to help with the

**Plate 16.2.** **A:** Mohammad Aatur Rahman (b.1925) as deputy director of the vaccine production laboratory in Dhaka, Bangladesh, played an important role in its development and, later, as health adviser to the Planning Commission, provided essential support for national mobilization for smallpox eradication in 1975. **B:** Karel Markvart (b. 1933) was a WHO adviser to the programme in Bangladesh from 1968 to 1971.

Notes: WHO records for 1967-1971 reflect support to both East and West Pakistan. Approximately half (the figures shown in parentheses in this table) was provided to East Pakistan. The principal contributors to the WHO Voluntary Fund for Health Promotion were Canada, Denmark, Norway, Sweden and the United Kingdom. The United Nations Relief Operation, Dacca (UNROD), provided US\$415 000; UNICEF provided US\$20 000.

<sup>a</sup> From Joarder et al. (1980) and WHO financial records.

<sup>b</sup> Estimated.

<sup>c</sup> Not including the cost of 45.3 million doses of vaccine.

<sup>d</sup> = data not recorded.

organization of the national mass vaccination campaign. The problems in mobilizing and training so large a staff were staggering. Additional government funds were required to implement the programme (2.5 million rupees—i.e., US\$ 250 000) but because the agreement was not signed by the government until April 1968 no funds were made available before the fiscal year beginning 1 April 1969. A full-time national counterpart—Dr A. M. Mustaqul Haq, an able and dedicated public health officer—was not assigned until July 1969.

In 1968, the organization of health services in 12 of the 19 districts was chaotic. In the 12 so-called "non-provincialized" districts, there was a dual management structure. A district council appointed and paid the salary of a district health officer, who was responsible for preventive activities, while the provincial government appointed and paid a civil surgeon, who was responsible for both curative and preventive activities. At the next lower level, the subdivision, health activities were under the direction of a subdivisional medical officer of health, appointed and paid by the provincial government. He was required to supervise sanitary inspectors, who were appointed and paid by district councils. In their turn, they were expected to supervise vaccinators, who were recruited and paid by the provincial government. In addition, municipal staffs were independently directed by municipal committees and were not responsible to provincial or subdivisional

government health staff. Appointments by district councils and municipal committees were as often decided by political considerations as by qualifications; discipline in performance and coordination were chronic problems which plagued the programme throughout its course. In the remaining 7 districts, the health services had been "provincialized" and there, with all health staff appointed and paid by the provincial government, the health structure operated more effectively.

At the end of 1968, the Dhaka municipal committee was persuaded to provide funds and staff to undertake a mass vaccination campaign, in part as a pilot study, but also in recognition of the role of this urban area as the country's principal focus of the spread of smallpox. The campaign was reasonably successful as measured by a vaccination scar survey; by the end of the campaign, more than 90% of the population had vaccination scars (Table 16.6). After May 1969, no smallpox cases were detected in Dhaka for more than 2 years.

Table 16.6. Dhaka Municipality: vaccination scar survey, 1969, by age group

Age group (years)	Number examined	% with vaccination scar
0-4	1 387	76.8
5-14	1 951	93.2
≥ 15	1 695	98.0
Total	5 033	90.4

Table 16.7. Bangladesh: vaccine production at the Dhaka laboratory and vaccine donations, 1972-1977

Year	Number of vials	
	Produced by the Dhaka laboratory	Donated by other countries
1972	343 380	26 000
1973	807 000	190 000
1974	963 500	453 000
1975	730 152	1 136 000
1976	458 750	0
1977	703 600	0

Vaccine production, meanwhile, proved to be an unexpected problem. The quantity of vaccine produced was less than had been expected and barely sufficient to supply East Pakistan. Between 1966 and 1971, the laboratory produced an estimated total of 4 million vials of freeze-dried vaccine. Vaccine quality was said by the laboratory director to be satisfactory, but when samples from 7 batches were tested in the WHO smallpox vaccine reference centre in Bilthoven, Netherlands, in late 1968, only 3 met the accepted standards. Thereafter, the director permitted no one to have access to the laboratory's records. He asserted that the vaccine was satisfactory, but examination of a further 10 batches in 1969 showed that only 3 were up to standard. Because of production problems, a consultant was recruited by WHO to work with the laboratory staff and after this the quality of the vaccine improved and the records again became accessible. However, some difficulties in producing a stable vaccine persisted throughout the programme.

Vaccine production data by year are available only for the period 1972-1977. The quantity produced was gradually increased after the provision by WHO of additional equipment and supplies, so that by 1973 more than 10 000 vials a week were being manufactured. Nevertheless, up to 1975, additional vaccine was required and this shortfall was met by a number of donors through contributions to the WHO vaccine reserve stocks (Table 16.7).

In April 1969, the government-funded posts for the vaccination campaign were finally established, but recruitment proved to be such a cumbersome procedure that not until January 1970 did sufficient staff become available to permit mass campaigns to begin in 15 of the 21 subdivisions in 7 of the country's 19 districts. In the execution of the programme and in the reporting of cases, it

was agreed that the divisional and district health authorities would be bypassed, thus streamlining the structure so that only 4 levels would be involved in administrative direction and case reporting—headquarters, subdivisions, *thanas* and unions.

The vaccination campaign made slow progress, however. By November 1970, the teams had vaccinated only 4.5 million persons, little more than 6% of the population of the country (Sommer et al., 1973). Meanwhile, local vaccinators reported that they had vaccinated 32.8 million people in 1968 and 31.6 million in 1969, although these figures were considered to be inflated. In 1970, vaccination scar surveys in the 7 districts in which mass vaccination had been performed showed 4 in which the proportion of the population with vaccination scars ranged from 64.9% to 72.1%, substantially lower than the 80.9% found by the research team in Comilla. In the other 3 districts, the proportions with vaccination scars were, respectively, 75.6%, 77.5% and 86.2%.

The number of reported cases reached a peak of 9039 in 1968, the highest total in a decade, but declined to 1925 in 1969. What, if anything, this implied was unknown since little had been done to improve the reporting system.

#### INITIATION OF SURVEILLANCE-CONTAINMENT AND THE INTERRUPTION OF TRANSMISSION, 1970-1971

It had been agreed that in addition to the vaccination staff, there should be a surveillance team for each subdivision in which the mass vaccination campaign was conducted. As the plan of operations stated, the team would (1) control any reported attack of smallpox, and (2) if no cases were reported, vaccinate any person who had been missed after the operational (vaccinator) group had left the area. This first official recognition that there should be surveillance teams was encouraging but, conceptually, still far removed from the objective of establishing teams solely responsible for developing the reporting system, detecting cases and containing outbreaks throughout the country.

In November 1969, a WHO intercountry seminar on smallpox was convened in Dhaka which illustrated, on the basis of reports from western Africa and Brazil, what could be

achieved with more effective case detection and outbreak containment. East Pakistan had reported only 4 cases in September and 1 case in October 1969. With so few reported cases, it was decided that from January 1970 an effort would be made to investigate every reported case. A surveillance section, headed by a medical officer, was established and 1 central and 4 divisional surveillance teams were recruited to improve reporting and to investigate outbreaks throughout the country. Because government travel allowances were too meagre to cover even the most modest board and lodging, WHO agreed to provide the teams and other senior supervisors with a supplementary per diem allowance to permit them to travel in the field. The leaders of the 4 divisional teams, Dr M. A. Sabour, Dr M. Yusuf, Dr M. Shahabuddin and Dr M. A. Khan, proved to be exceptionally able and dedicated and served in this capacity throughout the entire programme. In January 1970, the first monthly surveillance report was issued, and this series continued to appear, with interruptions due to civil war, throughout the programme.

Because the time of Dr Markvart and Dr Huq was fully taken with the complex logistics of the mass campaign, Arita was assigned from WHO Headquarters for the months of February and March to help to develop the surveillance programme. In collaboration with the newly constituted surveillance teams, he investigated reported outbreaks in various parts of the country. To the surprise of all concerned, the teams discovered that cases being reported from the central and southern parts of the country were not smallpox but chickenpox and other skin diseases. On the other hand, in a northern district, the investigation of a newspaper report of 6 cases led to the detection of 93 cases of smallpox. By the end of March, it appeared that smallpox was localized in only 5 northern districts of the country. Arita suggested that the vaccination campaign should be temporarily suspended in favour of an emergency surveillance-containment campaign whose objective would be to interrupt transmission before the monsoon rains. With the agreement of a newly appointed and highly competent Minister of Health, Colonel M. M. Haque, and after the surveillance teams had been specially trained, such a campaign began; it was one of the most dramatically successful of the entire global eradication programme.

To facilitate surveillance, the reporting system was changed. The detection and identification of cases had depended on a traditional routine in which a local government employee, the chowkidar (who served also as the village watchman), was responsible for the weekly reporting of births, deaths and notifiable diseases to the *thana* headquarters. The chowkidars were frequently illiterate, poorly paid and ineffectual. Reports received at the *thana* were forwarded by mail to the subdivision, and then to the statistical section of the Ministry of Health. Reports were submitted sporadically, often after delays of several weeks, through a mail system that was anything but reliable.

Beginning in April 1970, all health workers and the malaria eradication programme staff were asked to report each suspected case of smallpox they encountered to the *thana* sanitary inspector. The better-paid, better-supervised and generally more responsible malaria eradication workers visited all houses throughout the country once every 2 weeks, searching for persons with fever who might have malaria and confirming this by the examination of blood smears. For them to report suspected cases of smallpox entailed little additional work and no disruption of activity. *Thana* sanitary inspectors were instructed to forward weekly reports of all cases in their *thana* to the subdivisional medical officers. They in turn were to report cases by telegram rather than by mail to the Dhaka smallpox eradication programme headquarters. When outbreaks were detected, the subdivisional medical officers as well as the *thana* health inspectors were instructed to investigate and contain them. This system brought health workers into the reporting system and streamlined reporting by introducing telegraphic notification directly from the subdivision to the smallpox eradication headquarters, thus bypassing the largely uninterested bureaucracy of the statistical section of the Ministry of Health.

The investigation of outbreaks generally confirmed the findings of the Comilla study: that most outbreaks originated in cities; that the spread of smallpox from village to village was surprisingly infrequent; and that outbreaks could be readily contained by vaccinating the inhabitants of an infected *bari* and those of a few *baris* surrounding it. In the northern part of the country, in which health services were less adequate and vaccinal

Fig. 16.5. Bangladesh: typical seasonal variation in smallpox incidence, as shown by the number of reported cases in 1968.

immunity was lower, village-to-village spread was documented in 3 *thanas* in which 13 outbreaks and 149 cases had occurred. Even here, however, the spread of smallpox was slow and although 3–7 months had elapsed between the introduction of smallpox and its detection, there were comparatively few cases in each generation of transmission and the outbreaks were readily contained (*Wkly epidem. rec.*, 1970b). Between January and March 1970, 1024 cases were detected and reported but many of these represented cases which had occurred some months previously. Few active cases were discovered.

In the entire country, only 263 cases were detected in April and only 116 in May. Moreover, the cases were localized: 4 out of 19 districts accounted for all but 59 cases. In June, the 5 surveillance teams were assigned to work intensively in the remaining infected areas and 10 surveillance teams previously working with the vaccination teams were also sent to these areas to contain outbreaks. Thirty-eight cases were discovered in June, 23 cases in July, and 9 cases in August. In August, the teams detected and contained the last known outbreak—in Pabna District.

Effective surveillance continued for another 6 months but no further cases could be found.

In March 1971 civil war broke out, and until December 1971 the country was totally disrupted. During this period, it is estimated that between 1 and 3 million civilians died, 10 million refugees fled to India and an estimated 16.6 million people left their homes for other parts of the country (Chen & Rohde, 1973). Bridges were blown up, 1.5 million houses were destroyed, and severe famine occurred (Greenough & Cash, 1973).

Such evidence as is available substantiates the belief that, until 16 December 1971, when Bangladesh became independent, endemic smallpox was absent from the country—a smallpox-free interval of 16 months. During the period of civil war, no cases were found in any of the major cities, the usual sites of endemic transmission. The divisional surveillance teams were proud of their achievements and continued to travel widely throughout the country—albeit at considerable risk—seeking information about possible cases but finding none. The refugees who streamed ceaselessly across the border throughout this period were reasonably thoroughly screened by Indian civilian and military health staff in an effort to detect cases of smallpox, but none was discovered. Moreover, when smallpox was reintroduced into Bangladesh, investigation revealed that the primary source of each outbreak was a refugee who had contracted the disease in 1 of 4 infected refugee camps in India or on the way home. During April 1972, almost all cases occurred among returning refugees and their immediate contacts (Sommer et al., 1973).

The comparative ease and rapidity with which smallpox transmission was interrupted in Bangladesh in the summer of 1970 was in stark contrast to the staggering difficulties which were to mark the 4 years following its reintroduction. In retrospect, the timing of the 1970 spring surveillance-containment campaign had been ideal, from the standpoint both of the season and of the longer-term periodicity of smallpox. It had begun in the late spring, when rates of transmission customarily declined and many outbreaks terminated spontaneously (Fig. 16.5). With regard to the longer-term periodicity, smallpox incidence had peaked in 1968, with 9039 cases, and in 1969 the annual reported incidence had declined sharply to 1925 cases. In 1970, it is probable that no more than 150–200 cases would have been reported had not

**Plate 16.3.** Bangladeshis, infected with smallpox while living as refugees in India, returned to their newly independent country, only recently freed of smallpox, from December 1971. Travelling in crowded trucks and trains, many lived in resettlement camps until their houses could be rebuilt. Smallpox spread widely and rapidly through the camps and across the country.

the special programme improved the completeness of notification. Even so, only 1473 cases were recorded. Moreover, at this time, neither flood, drought nor civil disorder resulted in famine and the extensive refugee movements which were to mark succeeding years. In some ways, the success of the 1970 campaign had a negative effect by engendering an unwarranted degree of optimism that such a favourable outcome could be achieved as readily and as rapidly again in Bangladesh as well as in other parts of the subcontinent.

### THE REFUGEE CAMPS AND THE REINTRODUCTION OF SMALLPOX, DECEMBER 1971-MAY 1972

Of the estimated 10 million persons who left the country, most were housed in crowded camps. The largest, near Calcutta, was the Salt Lake Camp which sheltered an estimated 200 000-300 000 refugees. Government priority was given to supplying food, shelter and sanitary facilities. As noted in one report (Rohde & Gardner, 1973):

"The provision of relief to 10 million refugees ... represented a monumental humanitarian achievement. That mass starvation and galloping epidemics did not consume a greater portion of the refugee population is a tribute to the leadership, dedication and energy of the Indian Government ...

"In contrast to the efficient conduct of the overall relief effort, authority over health programs was not invested in any one group or person ... As a result, health policies and programs often lacked focus, direction, and coordination."

The provision of smallpox vaccination was one of these policies.

The Indian Ministry of Health had instructed state governments to ensure that all refugees were vaccinated against smallpox. In some camps, vaccinations were given by government staff and/or the personnel of voluntary relief agencies, and the conscientious performance of this task was confirmed by visiting Indian and WHO staff. However, state officials did not permit national health personnel or WHO staff to visit the camps in West Bengal so confirmation there was not possible. Medical care in the Salt Lake Camp was under the supervision of a voluntary relief agency; at that camp, as it was learned later, vaccination was ignored. It is likely that cases of smallpox began to occur in November, the source of infection being villages in

Sathianathan, a medical officer in Bangladesh, who had previously served as the WHO adviser for smallpox eradication in Nepal; A.K. Joarder, Assistant Director of Health Services of Bangladesh and director of the national smallpox eradication programme, 1972-1977.

West Bengal. The cases were recorded as chickenpox by the health staff.

The epidemic was discovered by chance. On 19 January 1972, an American epidemiologist thought he could identify cases of smallpox in a television film of the camp transmitted to the USA. He telephoned the Communicable Disease Center, which telephoned WHO Headquarters. WHO telexed the government of India, which in turn contacted the West Bengal Ministry of Health. Although the state Director of Health Services categorically denied there were cases, one of the national staff flew to Calcutta and immediately found numerous patients. The isolation of cases and vaccination began on 23 January, but by then it was too late. On 16 December 1971, Bangladesh had become an independent country and refugees began returning home forthwith. By mid-January, an estimated 50 000 had left the Salt Lake Camp. Infectious cases, patients in the incubation period and unvaccinated contacts were all loaded together on trucks for the trip to the border. It was the season when the transmission of smallpox was most rapid and with 26 million displaced persons moving from place to place, herded together in temporary camps and crowding the bustees (city slums), smallpox spread rapidly.

Under the best of circumstances the problem would have been difficult to cope with but at this time the health services were

seriously disrupted. So many motor vehicles had been damaged or stolen that less than half remained in working order, and only one-third of the number of bicycles required were available. Boats had been damaged or sunk and because of the destruction of roads, bridges and ferries, travel from place to place was difficult and time-consuming.

Arita, then on duty travel in India, flew immediately to Dhaka, and working with Dr M. Huq, the Director of Health Services, endeavoured to control the outbreaks. By March 1972, the smallpox eradication headquarters had been re-established under Dr A. K. Joarder, Assistant Director of Health Services; divisional surveillance teams had been reconstituted and were endeavouring to detect and contain outbreaks as best they could. Smallpox continued to spread, however, and 4 WHO epidemiologists were hurriedly dispatched. Among them were Dr Stanley Foster, who had previously served as the chief smallpox adviser in Nigeria, and Dr Nilton Arnt, one of the principal epidemiologists who had worked in the eradi-

cation campaign in Brazil. Some 3800 temporary vaccinators were hired to perform vaccinations, primarily in the large temporary refugee camps and surrounding districts. At first the epidemic was largely confined to 3 south-western districts—Barisal, Faridpur and Khulna. Active search, however, revealed the presence of smallpox in 27 of the country's 57 subdivisions, although most had only a few cases. The refugees were mainly Hindus and initially the outbreaks afflicted Hindu areas and villages, but within a few generations of disease transmission, other groups were infected as well. In March, epidemic smallpox was detected in Khulna Municipality, the third largest city in Bangladesh. The control of smallpox in urban areas was recognized to be vital, and here a vigorous and remarkably successful programme was begun on 28 April (Sommer, 1974; Sommer & Foster, 1974). Eight 4-man surveillance teams were organized and trained to identify infected cases through interviewing patients at the Infectious Disease Hospital and by visits to the bazaars. When a case was found in the city, all persons in the household and compound were vaccinated and house-to-house searches were conducted throughout the village or bustee. The area was revisited after 2 or 3 days and again 3 weeks later to vaccinate individuals who had been missed during the first visit and to be certain that transmission had stopped. Containment measures were necessarily limited in scope because of the paucity of staff and the extent of the epidemic. In fact, it was

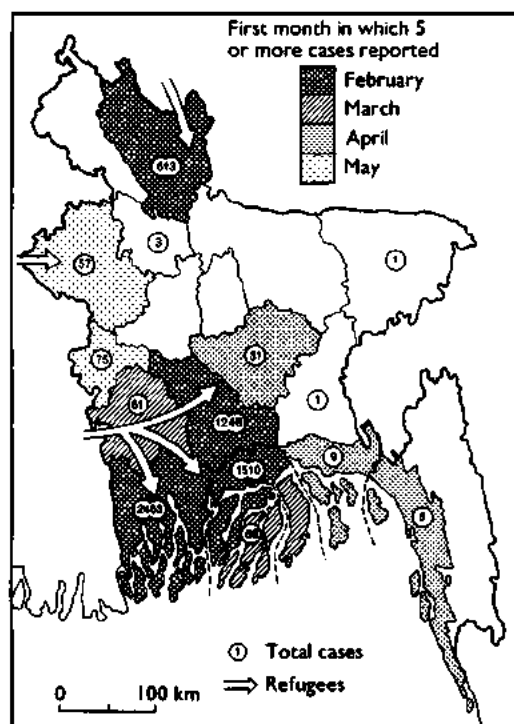

Fig. 16.8. Bangladesh: infected districts and number of reported cases of smallpox as of 30 June 1972.

necessary to divide the city into 3 segments and to deal with each in turn. Although 1073 cases were detected, smallpox was effectively contained within a matter of 4–6 weeks in each of the areas (Fig. 16.6). Meanwhile, the disease had broken out in a city refugee camp housing 30 000 persons. It was decided to vaccinate everyone in the camp by the simple expedient of making vaccination a prerequisite for the receipt of relief supplies. Altogether 233 cases were detected; however, the outbreak was as successfully dealt with as the one in Khulna Municipality (Fig. 16.7). To have achieved so much so quickly, with so few health personnel, at a time of considerable civil turmoil was a remarkable accomplishment and encouraged staff in the belief that

the flood of importations might yet be successfully contained.

However, smallpox was spreading rapidly through rural as well as urban areas, wherever returning refugees settled. A survey of one rural *thana* in May revealed 2298 cases among 250 000 inhabitants—approximately 1 case per 100 population. Meanwhile the disease continued to spread through refugee resettlement camps, some of which housed Bangladeshis of Bihari origin. From these camps, it spread to adjoining *thanas*. Small outbreaks developed in Dhaka and Chittagong but these were controlled. Intensive studies of a number of the outbreaks in which cases and deaths were thoroughly investigated revealed case-fatality rates of up to 28%, higher than those found elsewhere in the subcontinent and undoubtedly reflecting the extensive malnutrition then prevailing.

By the end of June 1972, 6144 cases had been reported in Bangladesh, of which 5834 (95%) were from only 4 districts (Fig. 16.8). Although reporting was recognized to be incomplete, it sufficed to indicate that large parts of the country had few or no cases. With a concerted effort such as had been made in Khulna and conducted throughout the monsoon period of diminished transmission, the staff hoped that the epidemic spread could be contained. Special assistance was given to the programme by the United Nations Relief Operation, Dacca, in the form of motor vehicles, boats, outboard engines and bicycles. WHO provided motor cycles and additional bicycles to facilitate the effort (Table 16.8). However, much of the transport served only to replace that which was worn out or had been destroyed during the civil war.

Of the 4 WHO epidemiologists who had assisted during the spring emergency, Dr Arnt and Dr Foster continued on permanent assignment in what proved to be one of the most arduous and taxing endeavours of the global eradication programme. They were soon joined by 3 other staff, who remained with the programme essentially full time

### THE PROGRAMME IS RE-ESTABLISHED, JUNE 1972– SEPTEMBER 1973

The reporting system, which required weekly telegraphic reports from each of the 57 subdivisions, was reinstituted in March 1972 (Foster et al., 1980). Reports to the subdivisions were provided through *thana* sanitary inspectors by government health assistants, each of whom worked in a union, the health assistant/population ratio being approximately 1 to 15 000. During the summer, 4-man surveillance teams, headed by a sanitary inspector, worked in each infected subdivision; in each infected *thana*, vaccinators were grouped into 3-man teams for

active search and containment. Particular emphasis was placed on the search in weekly markets by health workers using megaphones. This approach was later shown to detect approximately 80% of all outbreaks within an area of 65 square kilometres.

A mass vaccination campaign in the 4 most heavily infected districts had begun in the spring, but was stopped when it became apparent that it would accomplish little more than the 1970 campaign. As Dr Huq and his colleagues stated in a report dated October 1972: "It is now clear that eradication through mass vaccination is not feasible ... The orthodox principle of blind, systematic vaccination has already been given up."

Between June and October 1972, 400–800 cases were detected monthly, a substantial number for that season of the year. However, up to the end of October, outbreaks had been documented in only 88 of the 409 *thanas* in the country, and by then only 36 were still infected. By the end of 1972, 10 754 cases had been reported, approximately one-tenth of the number which had actually occurred, as a survey for facial pockmarks carried out 4 years later was to show (Hughes et al., 1980; Fig. 16.9; Table 16.9). The system for detecting and reporting cases, although well designed, lacked adequate supervision.

After the monsoon, with the season of high transmission approaching, it was decided to concentrate resources in the subdivisions of the 4 most heavily infected districts. A 10-man team, headed by an assistant health inspector, was assigned to each of the infected *thanas* to search for cases and to contain any outbreaks that were found. A national surveillance team with 5 assessment staff supervised these efforts and made repeated visits to the sites of outbreaks to ensure that they had been contained. Four surveillance teams, working under the supervision of the national eradication headquarters, travelled throughout the areas which had reported only a few imported cases to strengthen surveillance and to contain outbreaks.

The strategy was based on the assumption that smallpox would tend to remain localized in the areas already identified as infected. A key factor in the strategy was the control of smallpox in Dhaka, the capital and largest city in the country, and the potential focus of spread of smallpox into the largely smallpox-free areas of central and eastern Bangladesh. In April and May 1972, 26 cases had occurred among refugees in Dhaka but the outbreaks

<sup>b</sup> Including deaths related to cases reported in previous months.

were contained. Only a single case was recorded in July and another in August, but early in October scattered outbreaks began to occur in densely populated urban slum areas and resettlement camps, in which the night-time population densities were estimated to be as high as 195 000 per square kilometre, or 1 person to every 5 square metres. Twenty-nine cases were detected in October, 80 in November and 216 in December (Table 16.10). The containment of outbreaks in the densely congested areas seemed all but impossible short of an area-wide mass vaccination campaign.

In January 1973, Dr Ward assumed responsibility for the development of a special programme in Dhaka to control smallpox more rapidly. A municipal headquarters was established and 18 mobile surveillance units were formed.

● The Infectious Disease Hospital and the major graveyards of the city were visited daily to collect information on smallpox cases and deaths.

- Fixed check-points were established at transport terminals to collect information and to vaccinate passengers.
- Vaccination of the inhabitants of slum areas and refugee centres was carried out at night as well as during the day.

During 1973, 1 747 000 vaccinations were performed in Dhaka City alone, but the epidemic did not begin to abate until April. Although only 4907 cases were detected, it was apparent from the large number of deaths attributable to smallpox that there were many more cases than this—an estimated 14 000 or more.

Meanwhile, during the spring of 1973, 26 surveillance teams worked throughout the country; 5 of these were national teams each with responsibility for a region, 9 were district teams, 4 were municipal teams and 7 were assigned to the heavily infected subdivisions. Each team moved from *thana* to *thana* searching for cases in major markets, schools and selected villages. When an outbreak was discovered, local health staff were

mobilized to vaccinate the residents of the 30 houses nearest to those with cases.

The programme staff worked frantically to contain the outbreaks but, with Dhaka heavily infected, smallpox quickly spread across Bangladesh. The number of reported cases increased from only 1019 in December 1972 (Fig. 16.10) to 3919 in January 1973 and to 5282 in February; in February, cases were reported from every district in the country (Table 16.11).

The epidemic reached its peak in April and once again began to subside with the onset of the monsoon. The number of reported cases was substantially greater than during the preceding year, but since the number of surveillance teams had increased and notification was more complete, it was hoped that during the monsoon season transmission could be brought under control. To facilitate this, containment procedures were changed, since it was found that outbreaks were persisting because of failure to vaccinate household contacts who were absent during the day. Accordingly, each team was required

to carry out house-to-house vaccination in each infected village at night or in the early morning.

### REORGANIZATION OF THE HEALTH SERVICES, OCTOBER 1973

In October 1973, only 646 cases were notified. Reports were being received promptly from 95% of the subdivisions and there was increasing confidence that few outbreaks were being missed. On the assumption of an average of 4 cases per outbreak, it was calculated that there were perhaps 150-175 infected villages in the entire country. Dhaka was free of smallpox, as were most subdivisions of Rajshahi and Chittagong Divisions. To ensure a closer supervision of activities throughout the country, programme staff decided in October to set up 25 district surveillance teams, 1 for each of 19 districts and an additional team for each of the 6 largest districts. Each team, which consisted of 5 persons, led by a health inspector, was given transport (a motor vehicle, a motor cycle or a boat).

The plan experienced a serious setback, however, when in November, the government decided to suspend health activities temporarily in order to reorganize the health services. The field staff of the hitherto autonomous malaria eradication programme were to be merged with other health workers into a single integrated health care service. The new workers were to be called "family welfare workers", each assuming responsibility for a specific geographical area containing approximately 5000 people. The tasks assigned to them included preparing individual family health cards, registering married couples and births, performing smallpox vaccination, searching for cases of malaria and smallpox, and distributing vitamin A capsules and contraceptives, as well as providing health education and family-planning materials.

The integration of all health services had long been a tenet of WHO but practical approaches to its accomplishment had never been satisfactorily elaborated. Bangladesh's experience did not provide a model. A training programme was hastily concocted and, for a period of 4 weeks, virtually all health staff

except smallpox surveillance teams were withdrawn from the field for training. They returned to the field to begin a whole range of new and unfamiliar activities for which few of the necessary supplies were provided. Their first task, which required some 2 months to complete, was to prepare a separate health card for each family on which the name and age of each family member were to be listed. Despite the integration of field staff, however, 2 separate supervisory structures were left in place: the malaria eradication programme structure and the previous health service structure. Former malaria eradication staff and health service staff looked to their respective former supervisors for direction. The entire health service, which had not been functioning well, deteriorated further; many employees abandoned their jobs and returned to cultivating their small plots of land.

All activities—case detection, containment and vaccination—sharply diminished after November, but despite less adequate reporting by the health staff the number of cases which were detected doubled between October and December. Smallpox cases, widely but sparsely distributed throughout the country immediately after the monsoon,

suddenly began to occur in large numbers in the northern districts of Rangpur and Mymensingh (Fig. 16.11), both of which, up to then, had been free from the disease.

In December 1973, the surveillance system was modified to enumerate "infected villages" as well as the numbers of cases and deaths, a practice that had been adopted earlier in the year in several states of India. In Bangladesh, each village was designated infected until 6 weeks had elapsed after the onset of the last case. (India continued to use a 4-week interval until later that year.)

During the first 4 months of 1974, the number of infected villages increased from 309 in January to 949 in April (Fig. 16.12; Table 16.12). Rangpur and Mymensingh Districts accounted for 660 (69.5%) of the total. In April, Khulna Division, which had been the epicentre of smallpox after the return of the refugees, had only 41 infected villages. The concentration of resources and supervisory personnel in 1972–1973 in the initially heavily infected areas had been remarkably successful in stopping spread, but the programme in other areas had consequently received less attention. With the withdrawal of health staff from the field and

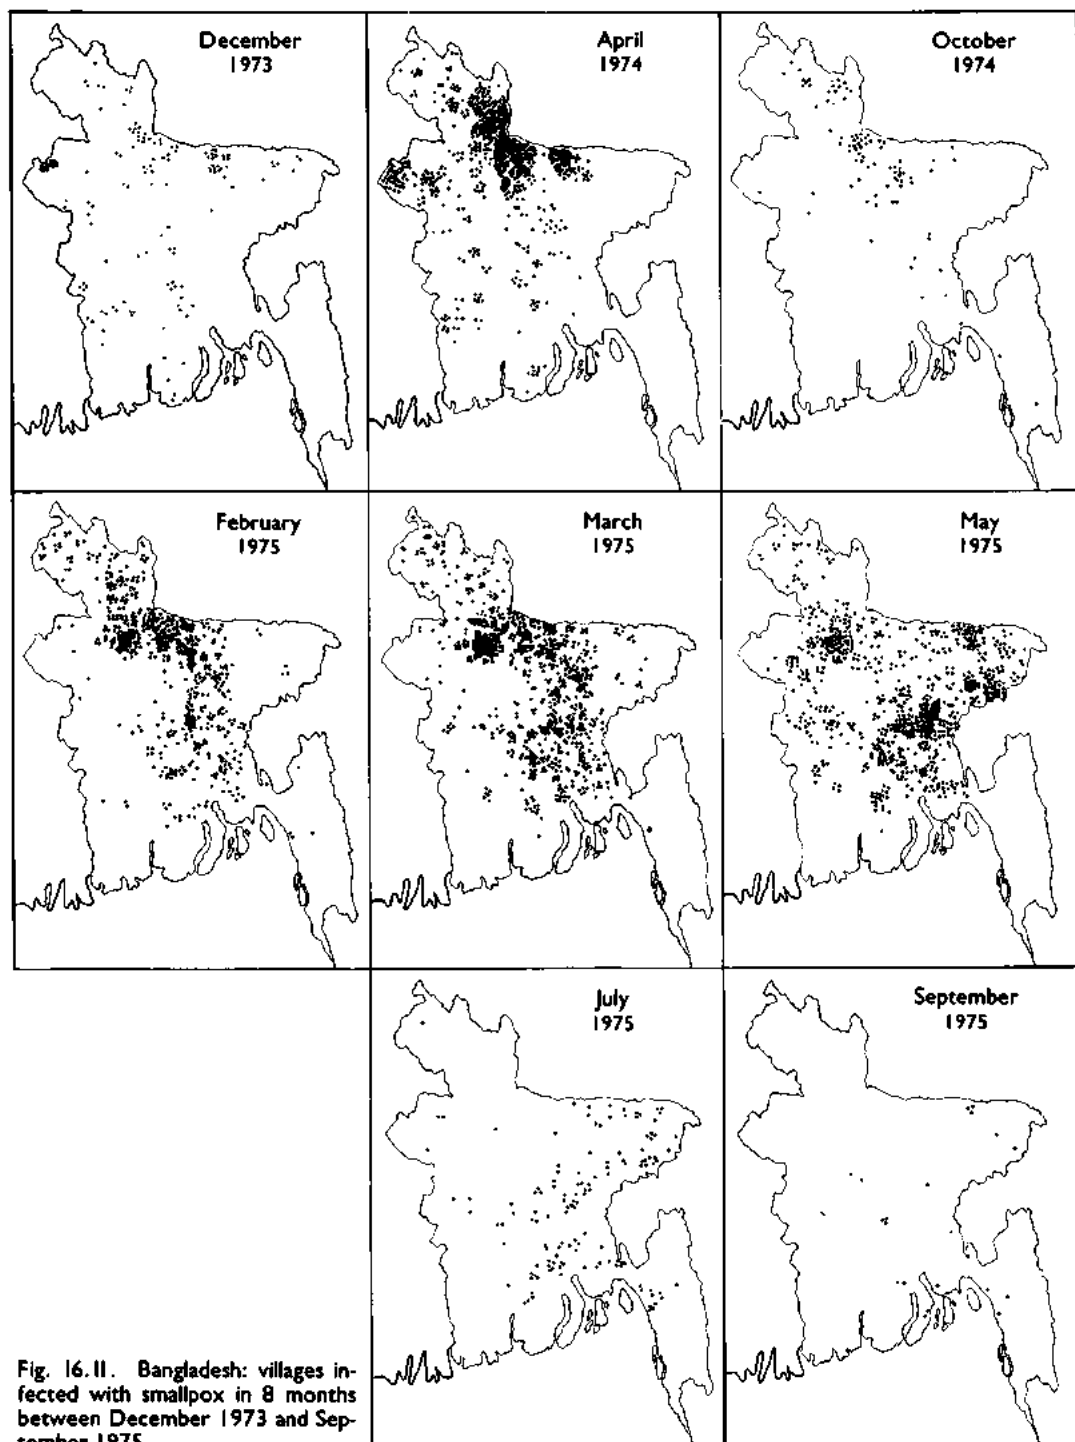

Fig. 16.II. Bangladesh: villages infected with smallpox in 8 months between December 1973 and September 1975.

**Plate 16.6.** A: Surveillance during the monsoon season was an especially arduous task as streams washed out roads, and foot-bridges often consisted of little more than a single bamboo pole. Schnur (b. 1948) served as a US Peace Corps volunteer with the smallpox eradication programme in Ethiopia from 1971 to 1974 before being recruited as a WHO consultant for service in India and Bangladesh.

the subsequent confusion accompanying the reorganization of health services, a potentially manageable situation had developed into a major problem.

#### **AN EMERGENCY PLAN FOR SMALLPOX CONTROL, APRIL 1974-JANUARY 1975**

By April, it was apparent to everyone that the integrated health service scheme was achieving little. A redefinition of the responsibilities of supervisors and workers and of the management structure was required. Accordingly, on 9 April the government issued a detailed "Emergency Plan for Smallpox Eradication under the Integrated Health and Family Planning Programme", of which an important component provided for unified direction of the health services. Dr Mahboob Rahman, former director of the successful national malaria eradication programme, was asked to supervise all health activities, including smallpox eradication. Within the new administrative structure, responsibilities specific to smallpox eradication were

defined. For operational purposes, new posts were created for staff at subdivision and *thana* levels. Civil surgeons, responsible for health matters in the subdivisions, were requested to appoint an area smallpox eradication officer for each of the 57 subdivisions and a *thana* smallpox eradication officer for each of the 424 *thanas*. In some areas, the incumbents were health services staff and in others malaria eradication staff. To assist family welfare workers in containment measures and to improve liaison with villagers, the order also authorized the temporary appointment and remuneration (6 *takas*, or about US\$ 0.75, per day) of an emergency field worker for each outbreak. The field workers were to be recruited and trained in the villages. The employment of emergency field workers afforded an unexpected bonus in that they provided temporary accommodation in the villages for smallpox programme staff.

When a case of smallpox was discovered in a village, the family welfare worker was to cease other duties and initiate containment, with the help of the emergency field worker, and to inform his supervisors. The family

Fig. 16.12. Bangladesh: number of smallpox-infected villages, by month, 1974–1975.

welfare worker was to reside in the infected village for not less than 10 days and to vaccinate all its residents as well as all persons living within a half-mile (800 metres) radius. The newly designated *thana* smallpox eradication officers were given the responsibility for organizing and coordinating all outbreak containment programmes. The area smallpox eradication officer was required to visit each *thana* not less than once a month and to send a weekly progress report to Dhaka.

A monthly national meeting of all area smallpox eradication officers was instituted to review progress and to decide on plans for the next month. As was the case in India, the meetings proved to be especially valuable in motivating staff, in providing continuing education and in allowing for an ongoing appraisal of progress and any necessary redirection of the programme.

Each week an epidemiological report of newly detected cases and deaths was compiled at the subdivision level and sent by telegram to the national headquarters. A more detailed written report was prepared every month.

Provision needed to be made for the isolation of patients in the densely crowded areas of Bangladesh. Here it was a more difficult problem than in many other parts of the subcontinent. In rural areas, the patients could be isolated in their houses, but in the urban slums and in refugee resettlement camps, they had to be isolated in a special facility. In the cities and towns of Khulna, Chittagong, Sylhet, Rajshahi and Dhaka, there were infectious diseases hospitals which provided for the isolation of cases but, as

elsewhere, they more often became centres for the dissemination of smallpox. Hospital superintendents rarely ensured that patients and visitors were vaccinated on entry. Consequently, smallpox eradication programme staff were obliged to organize and staff vaccination check-points at each hospital, sometimes with local police support. In heavily populated areas in which there were no hospitals, isolation wards or camps were set up in government buildings or even in tents, if necessary.

With 10 500 family welfare workers in the field, a defined supervisory and reporting structure, 25 special motorized surveillance teams, and 12 WHO epidemiologists, it seemed all but certain that transmission would be interrupted during the monsoon and post-monsoon period. Just 4 years previously, with far fewer surveillance teams, assisted by only 2 WHO epidemiologists, and a much less effective reporting system, transmission had been interrupted in less than 6 months.

The number of infected villages fell steadily, from 949 in April to 280 in August, of which 217 (78%) were in the northern districts of Rangpur, Rajshahi and Mymensingh. Even the distribution of the remaining outbreaks, similar to the pattern in 1970, suggested that the situation in 1974 might replicate that obtaining in 1970. The number of cases being detected remained high—1069

Plate 16.7. Mahboob Rahman (b. 1933), formerly director of the national malaria eradication programme, assumed overall direction of the integrated health programme in April 1974 and brought order to a chaotic administrative structure.

in August compared with 2110 in April (Table 16.13)—but detection was occurring earlier and more than 50% of all outbreaks consisted of only 1 or 2 cases. As an incentive for family welfare workers to report cases, it

was decided in August to offer a reward of 50 *takas* (about US\$6.50) to anyone who detected an outbreak. The system had proved successful in many states of India and its application at this time in Bangladesh seemed

appropriate. Additional help was provided by the United Nations Relief Operation, Dacca (UNROD), which was in the process of concluding its activities; it turned over to the smallpox eradication programme a central transceiver and 8 field radios. Six more field radios were added later and thus a valuable network of communication was established between the smallpox eradication programme headquarters and epidemiologists in the field.

In October 1974, only 91 infected villages remained, and periodic village-by-village searches were initiated. A similar search programme had begun in India a year before and more recently in Pakistan, but such searches in Bangladesh had not been possible before late spring because of the turmoil caused by the reorganization of the health services. During the monsoon months of 1974, national and WHO staff alike felt that searches were not required, in view of the existence of a unified health service and the assignment of a family welfare worker in each population unit of 5000 persons. Since each worker was expected to visit every house within his jurisdiction every 5 weeks and was motivated by the promise of a reward of 50 *takas* (about 5 days' pay) for the discovery of a case, it seemed unlikely that many outbreaks would be missed. The initiation of a search programme in October was intended as the first stage in the development of a scheme to confirm that transmission had been interrupted rather than as an operational tool to detect cases, as in India.

The late summer months, however, had brought still another tragedy to Bangladesh. The most extensive and severe floods for more than two decades swept through major

Plate 16.9. When isolation of smallpox patients in their own houses was not possible, hospitals were used, some of which were specially constructed, as was this one in Sylhet District.

### An Episode Indicative of Frustration and Misguided Effort

The climate of feeling in Bangladesh oscillated between optimism—that the interruption of transmission was only months away, an opinion prevailing in October and November 1974—to profound pessimism and doubt that eradication could ever be achieved. The early months of 1975 represented an extreme of the latter mood. Frustration and exasperation sometimes compromised judgement, as was exemplified in Bogra, a municipality and district in north-central Bangladesh.

By the autumn of 1974, Bogra District, once heavily infected, had interrupted smallpox transmission at the conclusion of a thoroughly competent but exhausting campaign. However, in late December 1974 and in January 1975, outbreaks began to recur following importations from the famine-stricken area to the north, and cases were detected in the municipality. The smallpox eradication staff were concerned about the prospects of wide dissemination of smallpox from an urban area and decided that a mass vaccination campaign throughout the city was urgently required. While such a scheme might seem attractive, similar efforts in the past had always proved costly in time and manpower and were rarely successful, in part because of the continual migration of the population. Following a 10-day house-to-house mass campaign, assessment revealed that only 50% of the inhabitants had been vaccinated. A second campaign proved no more successful. Yet a third campaign was organized, this time employing 3 WHO advisers who had been withdrawn from supervision of outbreak containment in rural areas. During the course of 2 weeks, with the staff working 15 hours a day, 7 days a week, a coverage of 93% was finally achieved. No sooner had this task been completed than a major privately sponsored fair opened which drew upwards of 20 000 visitors per day. Thenceforth outbreaks began to recur throughout the district, of which most could be traced to contact with infected persons at the fair. Efforts were made to persuade the organizers of the fair to close it down or to allow all those attending it to be vaccinated when they bought their tickets. The entrepreneurs, however, were also the principal civic officials and they were not anxious to discourage attendance by making vaccination a requirement. Six weeks of discussion were to elapse before the fair was finally closed by order of the central government. By then, Bogra was the world's second most heavily infected district. Not until May did smallpox begin to subside.

parts of the northern districts, where most of the remaining infected villages were located. Some refugees began to move from the area at that time, but in November and December, the season when crops were usually harvested, severe famine struck.

During the first week of October, only 24 cases were detected, but in succeeding weeks the numbers began to increase sharply. By mid-December, there were 168 infected villages, of which only 23 were outside the two flood-afflicted districts, but 20 outbreaks had occurred as a result of spread from these districts. Outbreaks were being detected unusually rapidly—55% within a week of onset and 88% within 3 weeks. The containment of outbreaks was not optimum but, still, in 84% of them no cases were detected more than 21 days after the onset of the first case.

Because of population movement and crowding, however, smallpox spread explosively. In Rangpur District, a beggar living in a market-place died of smallpox on 2 December; 48 second generation cases in 18 villages occurred among those who had visited the market. In Faridpur District, south of Dhaka, a fatal case in a village was the source of 37 second generation cases in 4 different villages (WHO/SE/74.65, Rangaraj & Yusuf). In mid-December, cases were discovered among famine-stricken refugees in Dhaka and in the district towns of Bogra and Mymensingh. Efforts to control the spread of smallpox among refugees sleeping shoulder to shoulder in the extensive slum areas of the cities was an all but impossible task.

The occurrence at this particular time of the most widely celebrated Muslim holiday,

**Plate 16.10.** Increasing numbers of staff and additional resources were provided to the programme in Bangladesh during 1974–1975 in a final intensive effort to eradicate smallpox from Asia. **A:** Andrew N. Agle (b. 1937), a veteran of smallpox eradication programmes in western and central Africa, 1966–1971, then in Afghanistan, 1972–1974, was the WHO administrative officer in Bangladesh. **B:** Jane Brown (b. 1942), seconded from WHO Headquarters for 6 months, directed radio communications. **C:** CARE, a private charitable organization registered in the USA, built an operations building, “Smallpox Zero”, to house additional programme staff. Additional buildings were constructed for the storage of parts and a garage for maintenance of a new fleet of Indian-made Jeeps.

the *Eid* festival (*Id ul Fetre*), further compounded the problem, since this feast was the occasion for large family gatherings, entailing extensive travel.

Meanwhile, in Nepal and Pakistan, transmission had been interrupted; in India, the incidence of smallpox and the number of infected villages were declining steadily. It became increasingly apparent that the course of events in Bangladesh would determine the success or failure of the endeavour to eradicate smallpox from Asia. Additional international staff were assigned to strengthen the programme in Bangladesh, the number increasing from 8 in June 1974 to 21 in January 1975. But smallpox continued to spread. As has already been mentioned, only 91 villages were infected at the end of October, but the number had increased to 130 by the end of November, to 223 by the end of December, and to 572 by the end of January. This last number was almost twice the figure recorded for the corresponding period one year earlier.

A catastrophe from the viewpoint of smallpox eradication occurred when the government decided that urban bustees should be demolished. In a matter of a few weeks, bulldozers and police dispersed an estimated 50 000–100 000 additional refugees from the cities throughout the countryside. Some had smallpox or were then incubating the disease. A frustrated, demoralized staff was called upon to regroup and to mount yet another national effort.

#### **NATIONAL MOBILIZATION FOR SMALLPOX ERADICATION, FEBRUARY 1975**

Beginning in December 1974, national health personnel and WHO staff stationed in Bangladesh, New Delhi and Geneva met repeatedly to decide on a revised strategy and additional measures that might be taken. With the extensive continuing movement of population, it was apparent that efforts would need to be greatly intensified, and that substantial additional funds would be required. However, WHO's Voluntary Fund for Health Promotion, as well as discretionary funds in the WHO regular budget, had been exhausted in strengthening the programme in India. Additional support would have to be sought, but this would require the approval by the Bangladesh Planning Commission of a

revised plan of operations and the concomitant financing. Although the Secretary of Health and the WHO Representative in Bangladesh supported the programme, they were of little help. Both were adamant that eradication could be achieved only through a national mass vaccination campaign conducted through the basic health service structure. They were not persuaded by the argument that this would be futile in an already well vaccinated population, nor could they accept the fact that the newly created basic health service structure had all but ceased to function. Fortunately, the recently appointed principal health adviser to the Planning Commission, Dr Mohammad Ataur Rahman, had a far better and more realistic understanding of the problem and the resources needed. Dr Rahman was a knowledgeable and skilful administrator and virologist who had played a key role in the development of smallpox vaccine production in Dhaka, and subsequently had closely followed the progress of the eradication programme. Through his efforts, the Planning Commission was persuaded to direct an appeal for assistance to a number of international agencies. The Swedish International Development Authority responded—as it had in India—most rapidly and generously, making available US\$ 3.5 million. Significant contributions were also made by Canada, Denmark, Norway and the United Kingdom.

In February 1975, a presidential directive was issued which declared smallpox to be a national emergency and ordered the mobilization of all available resources to assist in its eradication. Thirty-five Jeeps of Indian manufacture were hurriedly procured and driven to Bangladesh; others were loaned from other programmes. Additional radios, motor cycles, boats and outboard motors were obtained. Mr Rodney Hatfield, a young volunteer from OXFAM (a charitable organization registered in the United Kingdom), assumed responsibility for transport maintenance and repair; an old garage was transformed into a fully equipped workshop with a staff of 12 mechanics; and numerous Ministry of Health vehicles that had long been in disrepair were made roadworthy. An operations building was rapidly constructed by CARE (a charitable organization registered in the USA), using a new technique of jute and fibreglass construction. To coordinate field operations, WHO's former senior smallpox adviser in Afghanistan, Dr A. G. Rangaraj, joined the

staff. Dr Stephen Jones and Dr Donald Francis came from India to assist in adapting the most effective techniques employed there to conditions in Bangladesh.

Numerous other WHO staff and consultants were urgently recruited from countries around the world (Table 16.14), many of them having served in Africa, South America and other parts of Asia. It was a group remarkably diverse in nationality, being composed of Brazilian, British, Czechoslovak, Egyptian, French, Soviet, Swedish and Swiss citizens. The Center for Disease Control and OXFAM were especially helpful in recruitment. New colleagues arrived every 2 weeks, to rendezvous in New Delhi for a Monday briefing. On Tuesday they flew to Dhaka and over the next 3 days received intensive field and classroom training before being dispatched to the field. Because there was a shortage of hotel accom-

modation, a house was leased which could accommodate 18 persons—unofficially called WHOSE House (an acronym for World Health Organization Smallpox Eradication). By May, 71 international staff were working in the field, and during that month the recruitment of Bangladeshi epidemiologists from universities and other settings was initiated.

A formidable challenge was presented by the administrative coordination and financial monitoring of a programme which, operating with US\$12 000 a month in September 1974, was spending US\$125 000 a week by February 1975. This daunting task was capably handled by Mr Andrew Agle, who had served in the western Africa and Afghanistan eradication programmes and had joined the Bangladesh programme staff in September 1974. He and Mr A. Alim Mia, a Bangladeshi administrator

who had served with the programme since its inception, dealt with a considerable array of problems, both expected and unexpected. One of the more vexing was that of disbursing funds to the field epidemiologists for the payment of temporary staff to cover board and lodging, as well as petrol and repairs. The telegraphic transfer of funds to bank branches in peripheral areas would have been the most logical way of coping with the problem, but was technically impossible for many months. The only workable alternative approach was to disburse the funds at monthly meetings of supervisory field staff. However, the largest banknote then available was a 10-taka note (about US\$1.25) and, during the intensive period of activity, field staff were receiving 30 000 takas or more each month. The inevitably large bundle of banknotes was difficult to handle, but the problem was solved by using capacious gunny sacks and carrying them into the field tied to the back of a motor cycle; although there was no attempt at concealment, thefts never occurred.

Under the national mobilization plan, and with many additional field epidemiologists available, containment measures were greatly expanded from previous strategies which called for one family welfare worker and one emergency field worker to vaccinate everyone living within a half-mile (800-metre) radius of each case. The containment measures were basically the same as those that had evolved in India.

A worker who discovered a case was instructed to isolate the patient immediately

and to vaccinate all household members. A resident supervisor was appointed, usually the health worker in the area, who recruited 4 house guards responsible for keeping the patient in the house and for vaccinating all visitors. Food and water were provided if needed. (For the recording of activities, special "house guard books", such as had been used in India, were introduced in April.) The resident supervisor then hired 4–6 emergency field workers at 6 takas each a day. He trained them to register and vaccinate all residents and visitors within a half-mile radius of the infected house, and to search for cases in all markets, schools and houses within a 2-mile (3.2-kilometre) radius (Fig. 16.13). When these tasks were completed, the workers revisited all persons within the half-mile radius to detect and vaccinate any newcomers or others who had been missed during the intensive vaccination phase.

Resident supervisors were provided with a "containment book" in which the following information was recorded:

- a list of patients and the stage of their illness;
- information pertaining to the source of infection and contacts of the cases;
- a list of household members and temporary residents of Zones A and B (i.e., those living within a 100-yard (90-metre) and a half-mile (800-metre) radius, respectively, of the infected house);
- a list of staff and work schedules for all involved in containment;

### Dr A. B. M. Kamrul Huda

Dedication and sacrifice were characteristic of many who served the programme, and a few gave their lives. One young medical officer who did so was serving at the time as the Subdivisional Medical Officer of Health in Chittagong. He was notified late one night of possible smallpox on an offshore island and arose early the next morning to take a ferry to the island. Because of high winds the ferry was cancelled. Dr Huda was anxious to investigate the rumour and took a small local boat instead. The boat capsized en route and Dr Huda drowned. He died on 3 March 1975, leaving a wife and two young children.

- a record of visits of supervisory staff from *thana*, subdivision and district levels;
- a map of the outbreak area showing each house, all houses being numbered;
- a record of all financial transactions—e.g., payments to emergency field workers for petrol, etc.

Check-points were set up on strategic paths and roads to collect information about other areas in which cases might exist and to vaccinate passers-by.

The source of infection of each case was examined and all possible contacts were vaccinated. Any contact with fever was isolated and members of the household were vaccinated. Whenever the suspected source of infection was in another *thana*, or whenever a contact had left the village for another area, a special message (cross-notification) was sent by messenger, telegram or radio. District, subdivisional and *thana* officers, surveillance teams and epidemiologists made periodic surprise visits to assess the efficacy of the work.

At the monthly meetings of supervisory field staff, problems were reviewed and procedures changed as required. An example of an unexpected event was the discovery by a Bangladeshi epidemiologist, Dr M. A. Sabour, that in 11 out of 17 outbreaks for whose containment he was responsible, cases were recorded 15 days or more after containment had begun. As he discovered, most of the cases were relatives of patients and should have been identified and vaccinated. He learned, however, that when a family in an infected home was asked to give the names of all recent visitors, they omitted to mention the names of relatives—since relatives, in their culture, were not considered to be visitors. The steady improvement of containment could be measured by the diminishing proportion of outbreaks in which cases occurred more than 15 days after detection of the outbreak (Fig.

16.14). In November, cases occurred in 27% of the outbreaks more than 15 days after detection; by June, the proportion was less than 10% (Foster et al., 1980).

With increasing numbers of epidemiologists in the field to investigate the source of outbreaks, to trace contacts who might have left the scene of an outbreak and to discover rumours of outbreaks as yet undetected, many possible additional cases were identified in more distant areas. The radio network was used extensively to forward such information for other staff to investigate. Beginning in February 1975, each cross-notification was recorded and the results of the field investigations were tabulated (Table 16.15). Between February and December 1975, 1468 cross-notifications were transmitted, leading to the discovery of 28 previously unknown outbreaks—not a large yield for the number of reports transmitted and investigated but important, nevertheless, in hastening the interruption of transmission. Three addi-

tional outbreaks were discovered through notifications received from India.

### SPECIAL SEARCH PROGRAMMES

A special 6-day village-by-village search for cases had first been organized in October 1974 and a second was conducted in December of that year. It was believed that if the family welfare workers could be carefully instructed to perform well only one of their many assigned functions—i.e., that of smallpox case detection during a 6-day tour of their area—the results would be better than if this activity were but one of the numerous tasks required of them. *Thana* supervisors reported that the searches in October and December were reasonably successful but assessment by district and subdivision staff and surveillance teams indicated that there were large areas in which no search had been carried out and few in which searches had been conducted competently.

With additional staff to assist in supervision, some of whom had had experience with this technique in India, more energetic search programmes were introduced in April 1975; these were repeated every 4–6 weeks. Approximately 14 500 staff were engaged in each search, following special training programmes at each operational level.

The workers were asked to visit markets, tea-stalls and every 20th house. They were instructed to show the smallpox recognition card at each location, and ask the viewers whether they recognized the disease—which most of them did. The health workers were

told to inform their audience of the reward for reporting an unknown case of smallpox and where to report it; to record any information obtained about persons with rash and fever, including the deaths of any of them; and to report cases to the *thana* supervisor.

After each survey, 1500 villages were randomly selected to assess the efficacy of search. Assessment in Bangladesh was greatly facilitated by the fact that every house in the country was numbered—a practice begun by the staff of the malaria eradication programme and kept up by the smallpox eradication personnel. An assessment of the results of the April search revealed that surprisingly few villagers knew of the reward for reporting a case. On further investigation, it was found that health workers, wanting to claim the 50-*taka* reward for themselves, did not publicize it. This situation was corrected in May, when the reward was offered both to the person who reported the outbreak and to the first health worker to confirm it. The April assessment showed that only 30% of villagers knew of the reward, but by September this proportion had increased to 70%.

In contrast to the experience in India, the number of outbreaks discovered during each search was not high (Fig. 16.15). However, in India, the reward was not offered until many searches had been conducted, while in Bangladesh its existence was announced even before the first searches began. The searches in Bangladesh were more effective in increasing public awareness of the reward and in stimulating reporting than in detecting outbreaks. As an illustration, a review of the last 119 outbreaks which occurred showed that 55 (46%) had been detected by reports from the

Fig. 16.15. Bangladesh: number of outbreaks detected by week, 1975.

public and 37 (31%) by surveillance teams (Fig. 16.16).

The number of personnel engaged in the programme was far larger than it had ever been. An estimate during the 3-month period of greatest activity revealed that an average of almost 12 000 persons were working each day (Table 16.16).

Between February and April, the number of reported cases steadily increased, from 1703 in February to 2467 in March and to 3948 in April. Smallpox appeared to be as great a problem in 1975 as it had been in 1974 although, on the basis of later surveys, it was estimated that 83% of all cases were reported in 1975 compared with only 49% in 1974 (Hughes et al., 1980).

The occurrence of epidemic smallpox extending throughout Bangladesh for a fourth year was politically uncomfortable for the Secretary of Health, a former surgeon. He

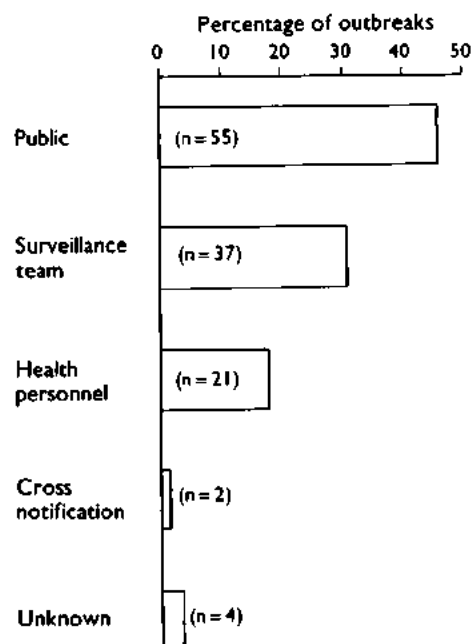

Fig. 16.16. Bangladesh: source of report of the last 119 outbreaks of smallpox.

fully accepted the idea of mass vaccination but was uneasy about the concept of a programme for detecting cases and containing outbreaks. The success of surveillance-containment operations in 1970 did not convince him. His personal experience with smallpox control in the Ministry had been confined to the period since Bangladesh's independence, and for the last 4 years optimism had been expressed by the staff during and immediately after the monsoon each year, but epidemics and emergency programmes inevitably followed in the spring. For advice he turned most often to the WHO Representative in Bangladesh, a public health physician but one who understood neither smallpox epidemiology nor the eradi-

Table 16.16. Bangladesh: personnel employed during the 3-month period of maximum containment of the smallpox eradication programme, May-July 1975

Personnel category	Number	Number of days per man per 3 months	Total number of man-days in 3 months <sup>a</sup>
Headquarters staff	80	75	6 000
Epidemiologists	90	90	7 200
Area and chana surveillance officers	500	30	15 000
Surveillance team members	400	75	30 000
Health staff for 2 searches	12 000	12	144 000
Containment:			
Health staff	1 000	70	70 000
Emergency field workers	10 000	90	900 000
<b>Total</b>	<b>24 070</b>	<b>-</b>	<b>1 072 200</b>

<sup>a</sup> The number of man-days per month totalled 357 400, or an average of 11 913 persons working every day.

cation strategy any better than the Secretary of Health. With smallpox incidence rising and with increasing international interest as to whether Bangladesh could or would be able to stop transmission, tensions were great. The Secretary of Health and the WHO Representative repeatedly and vehemently demanded that the surveillance-containment programme should be stopped and the entire population vaccinated forthwith. Dr Mahboob Rahman and his national and WHO colleagues argued that mass vaccination was futile, that vaccinal immunity was already high and that the surveillance-containment approach offered the only possible solution. Indeed, the level of vaccinal immunity, as shown in a 1976 national survey was 91% overall.

However, without notice to the programme staff, the Secretary of Health would periodically order the health staff in a district or subdivision to stop all other activities and to vaccinate everyone in the area concerned. Usually, this was accompanied by threats of punishment if any unvaccinated person was discovered at the end of 7 days or some such brief period. After lengthy discussions, the Secretary would eventually be persuaded to rescind the order, but, not infrequently, for many days outbreak containment programmes were abandoned and surveillance was stopped. Further problems occurred when the Secretary and the WHO Representative made one of their frequent visits to the field. The Secretary would announce that on his trip, he would stop at villages along his route and expect to find that every single person had been vaccinated. A flurry of activity ensued to vaccinate everyone along the route he was expected to follow, again at the expense of outbreak containment measures. An even more serious problem arose when he required senior staff to pledge to resign if cases of smallpox were found after a certain date, an action which resulted in the suppression of reports of cases. The problem was not finally resolved until April, when the WHO Representative returned to Geneva and was replaced by the able Dr Eung Soo Han. The Secretary's continuing concern about his and his country's image was reflected in May 1975 by his decision not to attend the World Health Assembly. Instead, he dispatched Dr Rahman to respond to the anxious inquiries he knew would be expressed about the Bangladesh smallpox eradication programme.

## THE FINAL CHAPTER

From April to August, the number of infected villages decreased at a substantially more rapid rate than in preceding years—from 1280 in April to 131 in July. The staff began to chart weekly the number of "active cases" still present—i.e., the number of cases in which the scabs had not yet been shed. In a progress report to WHO staff in July 1975, Henderson wrote: "Some years ago... we had plotted progress on a country and provincial basis, subsequently on a district basis and then by blocks/*thanas*. In now monitoring the numbers of individuals capable of transmitting infection, I believe we've reached a final stage." The last case in India, the last of 32 importations from Bangladesh, occurred in May, leaving Bangladesh the only endemic area in the whole of Asia. The search in July detected 33 outbreaks and that in August only 7. With the extensive resources available and a programme functioning so well, the end once again appeared to be in sight. There was, however, one further tragic event.

On 15 August, Sheikh Mujibur Rahman, the first President of Bangladesh, revered as the father of the country, was assassinated in a military coup. The airport was closed and the borders sealed. Communications by radio were suspended for 2 weeks and although field staff continued to work, movement in and out of Dhaka was limited. Fearing that vehicles might be seized, the smallpox eradication staff hurriedly dispersed them from the motor pool to locations all over the area. For nearly a month, most of the staff remained apprehensive that civil war might again occur and, with it, the movement of hundreds of thousands of refugees—and renewed epidemics of smallpox. India, meanwhile, greatly strengthened its complement of staff in border areas. Fortunately, the country remained quiet, the monsoon rains were plentiful, an excellent crop was harvested and the enormous movement of refugees ceased.

The post-monsoon period was not, however, without incident, as a Japanese scientific team arrived in Dhaka bringing with them a new laboratory technique for the rapid diagnosis of smallpox. It was a propitious moment at which to undertake the investigations, since Dr Farida Huq, a highly competent virologist, was present in Dhaka at that time and able to perform confirmatory studies on specimens from suspected cases. The new immunofluorescence technique seemed capa-

WHO / P. ROBERTS

**Plate 16.13.** Smallpox eradication programme offices in the field were simple but functional like this one in Chandpur Thana.

ble of identifying variola virus in pus or scabs within hours (instead of days) after a specimen had been submitted. Only 19 villages were infected in September as the team began its work, but many of the first specimens examined were reported as positive for variola virus. Surveillance teams were then taking many specimens from cases which they had diagnosed as chickenpox, simply to confirm by laboratory test that smallpox was not present. Many of these specimens were reported to contain variola virus and for weeks consternation and bewilderment prevailed as containment operations were begun and then stopped in numerous presumed outbreaks. There was a strong suspicion that something had gone seriously awry when immunofluorescence staining showed that material taken from a boil on the back of one of the WHO advisers contained variola virus. A technique which had worked well in the laboratory had failed when used in the field, and was soon stopped (Tarantola et al., 1981).

### THE LAST OUTBREAK

When the conflicting laboratory and clinical data had been resolved, it became clear that

smallpox transmission had apparently been terminated—the last known case having occurred on 14 September. Over the succeeding weeks, 8 previously undetected outbreaks were discovered in Patuakhali, Barisal and Dhaka but in none had cases occurred after 14 September. The monthly programmes of systematic search continued and, except in these three districts, independent assessment showed excellent results. At the beginning of November, civil disorder erupted, with local fighting breaking out in three different parts of the country. The United Nations was sufficiently concerned to recall its personnel to Dhaka. Only the WHO smallpox eradication staff remained in the field. But no additional cases could be found.

The progress of the smallpox campaign in Asia had been followed closely by the press, which believed, as did the personnel involved, that eradication of smallpox from Asia was the most formidable obstacle to global eradication. Early in November, 6 weeks after the onset of the last case, the only active outbreak in Asia was scheduled to be removed from the list. It was agreed, however, that caution was required and an additional 2 weeks should be allowed to elapse before an announcement was made. No cases occurred, and on 14

November 1975 WHO announced at a press conference that 2 months had passed since the onset of the last case in Bangladesh; and while the intensive search for cases would continue in Bangladesh and other countries, there was at that time no known patient in the whole of Asia, indeed in the world, with variola major. On the following day, 15 November, the eradication programme's telex control room received the following cable from the densely populated Bhola Island, off the southern coast:

"ONE SUSPECT SMALLPOX CASE DETECTED VILLAGE KURALIA [UNION COUNCIL] SOUTH DINGALDI [POLICE STATION] BHOLA DATE OF DETECTION 14/11/75 DATE ATTACK 30/10/75 CONTAINMENT STARTED DETAILS FOLLOW".

(The date of onset was later confirmed to be 16 October 1975.)

A team of epidemiologists immediately left Dhaka for Bhola Island expecting to find a misdiagnosed case of chickenpox. They reached the infected house only after a 24-hour journey by speedboat, steamer, Jeep, motor cycle and finally on foot. The diagnosis was not in doubt: it was smallpox, and this was confirmed days later by the laboratory. Everyone was concerned. It was November, the monsoon was over, and the season when smallpox was most rapidly transmitted was at hand. If there was one case, there had to be others in the chain of transmission.

Bhola Island, located at the mouth of the Ganges, had a population of 960 000 and an area of approximately 2600 square kilometres. Regular ferries connected the island with the mainland and other islands and these were heavily used.

In 1970, Bhola had been devastated by a tidal wave, which was followed by a relief operation that included a smallpox vaccination campaign. Because of this, the proportion of persons with a vaccination scar was higher than in most of the country. During 1974 and 1975, few smallpox cases had been reported. However, in August 1975, it was discovered that a medical officer had failed to report known outbreaks. Subsequently, surveillance had been reinforced, and since the beginning of August 141 cases and 33 deaths had been detected. All but 2 of the outbreaks, one of 43 cases and one of 44, had ceased before discovery. Once again, investigation revealed the suppression of reports and so, early in October, an additional surveillance team had been sent from another area,

the Bhola surveillance team reorganized, and an epidemiologist posted to the island for full-time work.

On 6 November 1975, while conducting a search of markets, the Bhola surveillance team received information about an outbreak in Kathali village. During the course of investigating and tracing the sources of infection, the team discovered outbreaks in 3 other villages with cases extending back to 2 March. A search began within a 5-mile (8-kilometre) radius of each of these villages. During a tea break in one of the markets, the surveillance team obtained information about the death of a person with rash in the village of West Joynagar, 5 kilometres to the south.

The death had been reported to the *thana* smallpox eradication officer, who had sent a family welfare worker to investigate. His conclusion had been that the death was caused by measles. On investigation, the surveillance team was in no doubt that it was due to smallpox. A search revealed an outbreak of 7 cases and 3 deaths. One of the patients was a heavily pockmarked 8-year-old girl who informed the team that there were other cases in Kuralia village, some 200 metres to the west of her house. Investigation there revealed 2 cases, one of which was in a 10-year-old boy whose onset of illness was on 6 October and the other in a 3-year-old girl, Rahima Banu, who had become ill on 16 October.

By the time of investigation, Rahima Banu was the only known patient with active smallpox in all of Asia. Accordingly, extraordinary efforts were begun immediately to contain the outbreak and to discover other possible cases. The surveillance team which had detected the outbreak was soon joined by teams of epidemiologists from Dhaka and other areas. A launch brought vaccine, light transport (motor cycles and bicycles), speedboat engines, drums of petrol, kerosene lanterns, loudspeakers and other equipment. The patient, who still had a few scabs on her legs, was isolated at home. House guards were posted 24 hours a day; food and money were supplied to the family so that no one would have to leave the house. Vaccination of the 18 150 people living within a radius of 1½ miles (2.4 kilometres) of the infected house was begun immediately. This task included day and night house-to-house vaccination, the enumeration of every household member, the checking of vaccination results, and the vaccination or revaccination of any newcomers to the village.

WHO/D. J. M. TARANTOLA

**Plate 16.14.** Rahima Banu, a 3-year-old girl from Bhola Island, Bangladesh, was the last case of smallpox in Asia and the last naturally occurring case in the world of variola major, the more virulent form of the disease. Her illness began on 16 October 1975, approximately 3 weeks before this picture was taken. The depigmented areas of her skin are sites where lesions were present.

The area within a 5-mile (8-kilometre) radius of the infected house was searched repeatedly by successive teams; each team searched for cases with fever and assessed the performance of the preceding team. The 7 markets and 9 schools, as well as all healers in the area, were visited repeatedly to pick up rumours of other cases. Each house on Bhola Island was searched by health staff under the guidance of epidemiologists and surveillance teams, which had been allocated specific geographical areas. This search also covered all public meeting-places such as markets, schools and tea-shops. Whenever it was reported that a member of any household in the outbreak area had left, the responsible authorities were notified so that the person concerned could be found, vaccinated and kept under surveillance.

A difficult problem was the poor means of access from the centre of the island to the shore, where most of the outlying villages could be reached only after a difficult journey by bicycle or on foot. Frequently, the paths leading to these villages were cut by small rivers caused by fluctuating tides. The settlements along the shore were occupied by landless peasants or fishermen, who were the most distant from health centres and the least likely to be visited by health staff. They were generally much less well vaccinated than other groups and unlikely to report any cases of smallpox. Accordingly, a dispensary-launch began a methodical village-by-village search, which had to be planned daily according to the tides. Local launches were used also.

A 500-taka (US\$33.00) reward was offered to anyone reporting a case of smallpox. This was widely publicized through the use of posters, pamphlets, handbills, loudspeakers and, from Dhaka, the press and other media. Check-points were established at such places as bus stations, ferry docks and crossroads, where travellers converged. Information was collected about cases with rash and these were checked by mobile teams.

About 10 kilometres north of the site of the outbreak, in Bhola town, a control room was established where progress could be recorded on maps and charts. Radio communication was established to permit regular contact between the control room, the dispensary-launch travelling along the shore areas, and Dhaka.

The health staff engaged in this outbreak alone (within a 5-mile radius) consisted of 3 epidemiologists and more than 40 health

WHO/P. ROBERTS, 1975

**Plate 16.15.** Mohammed Matiur Rahman (b. 1932), a medical officer with the national programme in Bangladesh, questioning villagers about possible smallpox cases during the search on Bhola Island.

staff and temporary workers. For the rest of the island there were 3 epidemiologists, and 180 specially deputed health workers to assist the subdivisional staff in the house-to-house searches. In addition, 16 emergency field workers worked at check-points and conducted municipal searches.

By 19 November, the fifth day after the discovery of the outbreak, the first round of vaccinations within the 1½-mile radius of the infected house had been completed. A second round was begun, covering the same area, and was completed 8 days later. Of a listed population of 18 150, 16 295 were vaccinated. A later assessment showed that 100% of the residents living within a half-mile radius and 95% of those living within a 1½-mile radius of the infected house had been vaccinated.

Meanwhile, 2 consecutive house-to-house searches within the 5-mile radius were completed by 8 December. Among the 120 000 population, 52 individuals with fever and rash were found, including 17 with chicken-pox and 11 with measles, but there were no cases of smallpox. During the following 2 months, 2 additional house-to-house searches of Bhola Island were conducted. During these operations, 2 more unreported smallpox outbreaks were discovered: one had occurred in 1974 and had resulted in 18 cases and 6 deaths; the second involved 1 person, who had become ill in July 1975.

At the end of December, the additional staff who had been sent to Bhola began to be recalled to their respective districts. Kuralia was declared smallpox-free and the 2-year post-epidemic surveillance period commenced.

### MORBIDITY AND MORTALITY DATA

To obtain precise data on the age distribution and case-fatality rates for smallpox, special studies were undertaken in 1976 to enumerate all cases and deaths in 165 outbreaks, including 115 that constituted the last outbreaks in the country, and 46 others, which were investigated in northern Bogra District. In all, 1127 cases were recorded (Table 16.17).

Cases occurred among all age groups but the youngest were the most heavily afflicted. Of the total, 55% occurred among children under 10 years of age, a group that made up only 34% of the population. Overall, the case-fatality rate was 18%, comparable to that in India. The much higher case-fatality rate among males over 20 years than among

females in the same age group was notable but no explanation was found for this disparity.

### CONCLUSIONS

The programme in Bangladesh was uniquely distinguished by extremes—with peaks of optimism and success alternating with catastrophic setbacks resulting from natural disasters of flood and famine and man-made disasters inflicted by civil war and the disruptive reorganization of the health services. The frustration and pessimism of the programme staff during the spring of 1975 were matched only by the feelings of their counterparts in Bihar State, India, 6 months earlier and are vividly depicted in the book *Quest for the Killers* (Goodfield, 1985).

The successful application of a surveillance-containment programme in the spring of 1970 had so rapidly and so easily interrupted transmission that it was difficult to believe that the success could not be repeated in 1972 or in the 2 succeeding years. In retrospect, the 1970 experience in Bangladesh to some extent paralleled events in India, where, for example, transmission was so rapidly interrupted in Tamil Nadu State (population, 41 million) in 1968 and in Gujarat State (population, 27 million) in 1971. These successful programmes engendered unwarranted confidence that transmission could be quickly interrupted in a population already reasonably well vaccinated and with so numerous a health staff available. What was not appreciated was the dearth of supervision of the host of health workers in many parts of India and in Bangladesh. Given optimum conditions of population stability, vigorous and enlightened senior programme leadership and the application of surveillance-containment

Table 16.17. Bangladesh: cases of and deaths from smallpox and case-fatality rates in 165 outbreaks, by age and sex, 1975

measures at a declining or low point in the long-term periodicity of smallpox, a modest surveillance-containment programme was rapidly and dramatically successful. When natural or man-made disasters created hordes of refugees, when leadership was deficient or when smallpox was at the height of its periodic wave, it became apparent that the health structure had little in reserve with which to cope with the situation.

Progress in programmes in the northern and eastern states of India had been disappointing and frustrating, but within little more than a year after the special intensified national programme began in September 1973, transmission was interrupted. In Bang-

ladesh, however, the interruption of transmission, once successfully achieved, was frustrated in each of 3 successive years by unexpected disasters. With courageous confidence, bolstered by material support from Sweden and other countries, a remarkably diverse national and international staff made one more heroic effort in 1975 and succeeded in attaining their goal. If civil war had broken out in August 1975, following the assassination of Sheik Mujibur Rahman, transmission would probably have persisted for at least another year and might perhaps still be occurring. History records, however, that Rahima Banu was the last victim of variola major—on 16 October 1975.

### INTRODUCTION

Progress in smallpox eradication throughout most of Africa was more rapid than in Asia, despite the fact that the majority of African countries had less developed health service infrastructures, poorer roads and communications and proportionately fewer health personnel. The rapidity with which smallpox was eliminated in an area embracing 21 countries of western and central Africa (Fig. 17.1) was especially significant. Programmes in all but one of the countries in this region were supported by the United States

Agency for International Development (AID) with technical direction and coordination provided by the United States Communicable Disease Center (CDC), later called the Centers for Disease Control. Most national programmes in this area began early in 1967 and all were fully operational by January 1968. By September 1969, every country except Nigeria had interrupted smallpox transmission, and in May 1970, only 3½ years after field operations had begun, the last case in this region was detected. Within this brief span of time, smallpox had been eliminated from some of the least developed and most

heavily infected countries in the world—from a contiguous area greater in size than the continental USA, inhabited by 111 million people (the estimated population in 1967).

From November 1965, when the USA decided to support the smallpox eradication effort in western and central Africa, this programme played a pivotal role in the ultimate achievement of global eradication. The resolve of the USA to commit substantial resources lent encouragement to the Nineteenth World Health Assembly's decision in 1966 to embark on the Intensified Smallpox Eradication Programme. Programme staff made important early contributions to the development and improvement of field operations; their observations changed the understanding of the epidemiology of smallpox and served to alter the global strategy. The demonstration that smallpox could be eliminated rapidly throughout such a vast developing area provided a crucial impetus to programmes in other countries and convincingly

showed that the goal of eradication was realistic, even in areas in which health services were the least adequate and in which difficult problems—even civil war—had to be surmounted. Finally, many individuals who acquired experience in this regional programme subsequently made important contributions to the development and execution of programmes in other parts of the world.

The activities and decisions leading to the development of this endeavour are thus of particular significance. Interestingly, despite the importance of the programme, the USA's decision to contribute to it did not result from a considered policy judgement to support the WHO Intensified Programme as such. Rather, it began as an ancillary objective in a multi-country programme for the control of measles in many of the less populous countries of this region.

After the programme had begun, the staff of CDC bore full responsibility for its technical guidance and coordination, although they

### Changes in Political Status and Names of Countries

In 1967, when the AID-supported regional programme began, all but 2 of the 21 countries (Equatorial Guinea and Guinea-Bissau) shown in Fig. 17.1 were independent States. Liberia had enjoyed sovereignty since 1847 but 18 others had become independent between 1957 and 1965. Thirteen had been colonies of France and were commonly referred to as francophone countries. These were the Central African Republic, Chad, the Congo, Côte d'Ivoire, Dahomey, Gabon, Guinea, Mali, Mauritania, Niger, Senegal, Togo and Upper Volta. Cameroon, which had been administered jointly by France and the United Kingdom, was officially bilingual. Four—namely, the Gambia, Ghana, Nigeria and Sierra Leone—had recently obtained independence from the United Kingdom.

Equatorial Guinea (population in 1967, 278 000), a colony of Spain, became independent in 1968 and subsequently received supplies and equipment from the USA for smallpox and measles vaccination. Guinea-Bissau (population in 1967, 525 000), a colony of Portugal, became independent in 1974 after assistance from the USA to the regional programme had terminated.

Two countries changed their names after the programme's conclusion. Dahomey was renamed Benin in 1975, and Upper Volta was renamed Burkina Faso in 1984. In this chapter, which describes activities before 1975, the former names, Dahomey and Upper Volta, are used.

kept in close contact with WHO staff responsible for the global programme. WHO's contributions were modest, consisting mainly in the provision of bifurcated needles, an average annual subvention of US\$200 000 to cover local costs, technical support to one programme (Mauritania) and the organization of activities pertaining to the certification of eradication in 1976. The remarkable achievements in this part of Africa are therefore primarily those of the national governments and staff, AID and the personnel of CDC.

### THE REGION OF WESTERN AND CENTRAL AFRICA

Within the region defined in this book as western and central Africa were 21 countries, of which 14 reported cases of smallpox in 1966 (Table 17.1). The predominant form of smallpox was variola major with a case-fatality rate of 5–15%. Because established health services were few and reporting was very incomplete, the actual geographical extent of smallpox and its true incidence were uncertain when the programme began.

The region was diverse both in ecology and in culture. Rain forests predominated along

the coast, giving way to savanna and finally to the Sahara desert. Throughout the region, hundreds of tribal groups speaking their own local language were organized into various tribal and theocratic societies which often transcended national boundaries. Road systems were generally poor, communications were difficult, and newly created governments were only beginning to cope with the array of problems associated with the development of education, agriculture, industrialization and health services. Smallpox was but one of many problems for which resources were few and trained manpower was limited.

CDC and WHO staff were in agreement that if smallpox could be eliminated from this entire region, importations would be infrequent and their containment would probably not present a serious problem. To the north lay the Sahara desert and the smallpox-free countries of Morocco, Algeria and Libya and the Spanish province of Western Sahara. To the east was the Sudan, then free of smallpox. To the south-east of the region was the Democratic Republic of the Congo (later renamed Zaire), the only adjacent country infected with smallpox. It bordered on the Central African Republic and the Congo. The latter two countries, in 1966, were thought to be smallpox-free and there were few travellers

from the Democratic Republic of the Congo into either of them because of the difficult terrain and political restrictions on travel.

In countries which had formerly been colonies of the United Kingdom, health care was provided primarily through government or mission health centres or dispensaries, some of which performed smallpox vaccination using glycerolated or lanolinized vaccine produced in Nigeria or the United Kingdom, although many offered no immunizations whatsoever. Mobile health units periodically augmented the vaccination effort in Ghana and in parts of Sierra Leone and southern Nigeria. The control of smallpox outbreaks was the delegated responsibility of district or local medical officers and, in some instances, mobile medical field units. As in other countries, the health personnel responded with varying degrees of interest, but even where efforts were made to control smallpox, these were frequently unsuccessful because of the use of the heat-labile, sometimes low-potency vaccine. Of the countries relying on this approach, only Ghana and the Gambia had succeeded in achieving a substantial measure of smallpox control. Ghana's success could be attributed to its mobile medical field units and to health inspectors who took special care in preserving the thermolabile vaccine and who diligently investigated and contained reported outbreaks by vaccination. The Gambia, too small in area and population to permit long-sustained transmission of smallpox on its own, was partially insulated from importations by the

surrounding, comparatively well vaccinated population of Senegal. Liberia, in which a mass vaccination campaign with freeze-dried vaccine had been conducted in 1962, followed by a WHO-supported programme, reported few cases. In northern Nigeria and Sierra Leone, however, vaccinia immunity in 1967 was especially low and smallpox was a serious problem.

In the former French colonies, disease control was primarily the responsibility of multi-purpose mobile teams of the local endemic diseases control service (*Service des Grandes Endémies*), which systematically moved throughout the country endeavouring to reach each village once every 2-3 years (Richet, 1965; Labusquière, 1967). Government health centres and dispensaries also existed but were less numerous and generally less well supported than in the former British colonies; mission hospitals and health centres were few. The multi-purpose teams administered smallpox vaccine and undertook other preventive measures, such as those aimed at controlling yellow fever, trypanosomiasis, yaws and leprosy. In most of the countries, a French-produced, freeze-dried vaccine had been used since the early 1920s (Fasquelle & Fasquelle, 1971). The degree of potency and stability of this vaccine is unknown, but when freeze-dried smallpox vaccine of reasonably high titre began to be used extensively in the early 1960s, and in areas in which the multi-purpose teams continued to function, smallpox incidence declined rapidly; in some countries, the disease had disappeared by

**Plate 17.1.** Villagers in Côte d'Ivoire line up for smallpox vaccination during the campaign that eliminated smallpox from that country in 1966.

1967. Thus, the numbers of reported cases in 1966 were few or nil throughout the former area of French Equatorial Africa (Cameroon, Central African Republic, Chad, the Congo and Gabon), as well as in Mauritania, Senegal and Upper Volta. In Mali, a WHO-supported programme begun in the early 1960s had markedly reduced smallpox incidence, and in Côte d'Ivoire specially constituted mobile smallpox vaccination teams interrupted transmission in 1966. In the other francophone countries, multi-purpose teams functioned less effectively, and in some of them had ceased to function altogether; in Dahomey, Guinea, Niger and Togo, smallpox continued to be an important problem.

#### **ORIGINS OF THE REGIONAL PROGRAMME, 1961-1965**

The decision by the USA in November 1965 to support a region-wide programme of smallpox eradication and measles control had its origin in a small-scale field trial of the newly developed Edmonston strain measles vaccine, which was conducted in 1961 in Upper Volta (Meyer et al., 1964a). This

vaccine had been found to be safe and effective when given to children in the USA but because it frequently induced high fever, gamma-globulin was given simultaneously to diminish symptoms. Under the difficult field conditions in developing countries, the administration of both the measles vaccine and gamma-globulin was not feasible. Both had to be given subcutaneously, and while a jet injector could be used to administer measles vaccine, a needle with syringe was required for the more viscous gamma-globulin. Expense was another factor, the vaccine and gamma-globulin costing nearly US\$2.00 per dose. Most developing countries could not afford to spend scarce foreign exchange on vaccines costing even a small fraction of this amount.

In 1960, Dr Paul Lambin, Minister of Health of the newly independent country of Upper Volta, was told of the new vaccine while visiting the United States National Institutes of Health (NIH). Because of the severity of measles in African children (Morley, 1962; Cantrelle, 1965), the vaccine was of special interest to him. Accordingly, he proposed that a study should be undertaken in Upper Volta to determine whether the

WHO/P. N. SHARMA, 1961

**Plate 17.2.** Paul Lambin, Minister of Health of Upper Volta (Burkina Faso), obtained support from the USA in 1961 for a national measles vaccination campaign. This was followed by similar campaigns in other francophone countries of western Africa and, eventually, by the smallpox eradication and measles control programme assisted by AID in 20 countries of western and central Africa.

measles vaccine without gamma-globulin could be given safely to African children. Concern about its safety was legitimate, since it was feared that the high fever it induced might prove harmful or even fatal to children suffering from such conditions as tuberculosis or malnutrition.

With support from NIH, Dr Harry Meyer and his colleagues studied a group of 600 children in Upper Volta in 1961 (Meyer et al., 1964a). They demonstrated that the vaccine without gamma-globulin could be administered with safety and efficacy. Dr Lambin was impressed by the results and requested the USA to provide support for measles vaccination for all young children throughout the country. This request was granted and between November 1962 and March 1963, the multi-purpose mobile teams of the endemic diseases control service in Upper Volta, assisted by Dr Meyer and his colleagues, vaccinated 731 548 children (Labusquière, 1967). The number of reported cases of measles declined sharply, and during the next 2 years remained well below previously recorded levels.

Information about this campaign was widely communicated by Upper Volta to other member countries of a regional health

organization, the Organization for Coordination and Cooperation in the Control of Major Endemic Diseases in West Africa (Organisation de Coordination et de Coopération pour la Lutte contre les Grandes Endémies en Afrique de l'Ouest—OCCGE), whose headquarters were in Upper Volta. The organization comprised most countries of the former area of French West Africa (Côte d'Ivoire, Dahomey, Guinea (until 1965), Mali, Mauritania, Niger, Senegal and Upper Volta). At the request of OCCGE, AID agreed to support additional national campaigns, and thus it was arranged for Dr Meyer to conduct training and demonstration projects in 6 of the countries (Côte d'Ivoire, Dahomey, Guinea, Mali, Mauritania and Niger) late in 1963. During the following year, AID allocated US\$1 478 000 for the provision of vehicles, jet injectors and measles vaccine to vaccinate 25% of the children between 6 months and 6 years of age. Towards the end of 1964, the measles vaccination campaigns began.

AID staff had assumed that the execution of the campaign would be comparatively straightforward, given the success in Upper Volta and the long experience of the multi-purpose mobile teams in each of the countries. The fact that not all the endemic diseases control services were of the same quality as that in Upper Volta was not appreciated. The ensuing difficulties were compounded by the problem of introducing a new technology—the jet injector—which at that time required electric power and was difficult to repair and maintain, and a new vaccine, which had to be refrigerated until reconstituted for use. To conduct the mass measles vaccination campaigns, most countries curtailed or stopped the activities of the multi-purpose mobile teams because national resources were too limited to permit the two sets of activities to be continued.

With the beginning of the mass campaigns, it was decided that such technical assistance as might be needed from the USA should be provided by CDC, the agency primarily concerned with the field implementation of disease control programmes. Thus, in December 1964, Dr Lawrence Altman of CDC was requested by AID to spend 6 weeks in the countries to observe the campaigns and to report on progress. He found few of the campaigns to be progressing at all satisfactorily and eventually spent 6 months endeavouring to bring order out of chaos, albeit with little success.

Despite the difficulties, AID decided to offer assistance to an additional 4 countries (Cameroon, Central African Republic, Chad and Togo) to permit them to begin mass measles vaccination campaigns in 1965-1966. The potential scope of the project was even further expanded when, late in June 1965, the manufacturer of the measles vaccine brought the persuasive Dr Lambin to the USA on a special tour. The Director of AID was impressed with Dr Lambin and asked that a plan be drawn up for a comprehensive programme of assistance for measles vaccination in 16 African countries, including all the former French colonies of western and central Africa, as well as the Gambia, Liberia and Sierra Leone. Recognizing that this implied the need for more technical assistance staff than had been foreseen, AID asked CDC whether 9 epidemiologists could be made available in the autumn of 1965, each to serve on temporary duty for periods of 4-6 months in the countries in which campaigns were either in progress or due to begin.

### **The Addition of Smallpox Eradication as an Objective**

Until July 1965, CDC personnel had not been involved in the development of policy or plans for the measles vaccination campaigns. However, if CDC were to provide so many epidemiologists for such extended periods of time, its own programmes would have to be curtailed or substantially altered. Accordingly, an examination of priorities and alternatives was undertaken, a responsibility assigned to Henderson, then Chief of the CDC Surveillance Section, from which most of the epidemiologists would be drawn.

To Henderson and his colleagues, the programme, as then conceived, did not represent sound public health policy. AID foresaw a 4-year programme during which each year all children from 6 months to 6 years of age would be vaccinated against measles in one-fourth of each country. At the conclusion of the programme, AID staff reasoned that all children would have been vaccinated and that the country would assume responsibility for continuing to vaccinate children who were born after the programme had terminated. It seemed unreasonable to CDC staff to assume that the impoverished African countries would be able to bear the recurring expenditures, given that measles vaccine then cost

more than US\$1.00 per dose; indeed, at that time, few of these countries could afford yellow fever vaccine, which was one-tenth as expensive. Had it been possible to eradicate measles from the area, vaccination conceivably could have been stopped, but this objective appeared unrealistic given the fact that no industrialized country, despite greater health resources, had yet eliminated the disease. At best, the reduction in measles incidence would be transient because almost all cases of measles in Africa occurred among young children and thus, within 3-4 years after vaccination in an area, measles incidence could be expected to approach levels comparable to those observed before the programme had begun. To embark on such a programme implicitly raised public expectations that the vaccine would continue to be made available as a routine preventive measure. If a government were to terminate its use abruptly after 4 years, possible repercussions from the public could be foreseen, particularly in the wake of the measles epidemics that would almost certainly follow.

In July 1965, however, the USA had already undertaken to provide assistance for measles vaccination campaigns in 11 western and central African countries; a proposal from CDC that no programme should be conducted was not acceptable. The combination of this programme with one designed to eradicate smallpox from the region appeared the most logical move, since it would provide an objective which offered hope of longer-term benefits. That the eradication of smallpox throughout a geographical region was feasible had been shown in other parts of the world. If this could be achieved, occasional cases might still be imported into the region and these would have to be contained. Smallpox eradication, however, seemed to be a more reasonable long-term goal than one which called for a continuing campaign of measles vaccination for all children. Moreover, as CDC staff reasoned, WHO and its Member countries were committed to a programme of global smallpox eradication and, although this was not progressing well, it was believed that a successful regional effort in one of the most highly endemic areas would represent an important contribution and perhaps a stimulus to other endemic countries.

Two other considerations—one technical and one political—also lent support to the idea of smallpox eradication. In 1965, CDC

had just completed a series of studies which demonstrated the efficacy and practicability of the intradermal administration of smallpox vaccine utilizing a newly developed nozzle for the jet injector (Millar et al., 1969; Neff et al., 1969; Roberto et al., 1969; Millar et al., 1971). The jet injector itself had been redesigned so that it could be powered by a pedal-operated hydraulic pump rather than by electricity; this offered a substantial advantage in field work. A second important consideration was the commitment made by the USA in 1965 at the Eighteenth World Health Assembly to provide support to the Intensified Smallpox Eradication Programme (see Chapter 9). Although the support then envisaged was for the development of a vaccine production laboratory in Kenya and assistance to smallpox eradication programmes in South America, it seemed reasonable to propose a broader initiative.

CDC therefore suggested that AID should support a region-wide programme of small-

pox eradication in western and central Africa, with measles vaccination also being offered in countries selected by AID and where it was agreed by national authorities. This was a much bigger programme than that envisaged by AID, which had anticipated providing support to only 16 countries, with a total population of about 50 million in 1967. Two important countries in the region which were not then included—Nigeria and Ghana—together had a population of more than 60 million (see Table 17.9).

The proposal was strongly endorsed by officials of the United States Public Health Service—Dr Luther Terry, the Surgeon General, and Dr James Watt and Dr Benjamin Blood of the Office of International Health. AID readily accepted the proposal for a programme dealing with smallpox and measles in 16 of the countries but not for the inclusion of Ghana and Nigeria. As noted in an AID memorandum of 19 July 1965:

"The total scope of the African problem is too great for any one donor to undertake its solution... With a few exceptions [the 16 countries are among those] in which a modest demonstration of US interest and presence is desired without involving the USA in major dollar or personnel expenditures."

Despite these reservations, planning by CDC staff proceeded throughout the summer for an 18-country programme of 5 years' duration which would provide all supplies and equipment, plus a complement of CDC technical staff for work in individual countries, in an African regional office and at CDC headquarters in Atlanta. If accepted, this would be the first AID-supported technical assistance programme to be administered by CDC. On 20 August 1965, after many discussions between CDC and AID staff, the full proposal was formally submitted to AID. At the suggestion of CDC, Mr Milton P. Siegel, an Assistant Director-General of WHO, and Dr Karel Raška, Director of the Organization's Division of Communicable Diseases, visited Washington to discuss the proposal, and, early in November, the Director-General of WHO, Dr Marcolino Candau, also had meetings with AID and CDC staff. Everyone urged that the plan should be implemented, although a point at issue was whether WHO or perhaps another donor could support the programmes in Ghana and Nigeria. WHO officials stated that the Organization's resources were inadequate for the

BY COURTESY OF J. D. MILLAR, 1968

**Plate 17.3.** J. Donald Millar (b. 1934), a CDC epidemiologist, directed the AID-supported programme for smallpox eradication and measles control in western and central Africa from November 1966 to March 1970. As Chief of the CDC Smallpox Unit, he had supervised field studies of the jet injector and demonstrated its usefulness in large-scale programmes. He is holding a fetish statue of Sopena, a smallpox deity of some tribes of western Africa.

undertaking, and on the basis of WHO's experience with respect to voluntary contributions from national sources, little hope was offered that the necessary support could be found elsewhere.

AID was faced with a dilemma. Commitments had already been made for measles vaccination campaigns in 11 countries for which technical assistance was needed. It was difficult to find the requisite complement of technical staff at short notice except from the Public Health Service, but this the Public Health Service declined to provide unless all 18 countries were included in a programme that provided for smallpox eradication. The issue was settled, partly in response to a memorandum from the Public Health Service (see box), and the offer of assistance was formally announced on 23 November 1965. Thus began the first coordinated regional smallpox eradication programme.

#### GOVERNMENT AGREEMENTS AND ORGANIZATION OF THE PROGRAMME

The proposal for the regional programme envisaged that it would begin in January 1967, little more than 13 months after the decision had been made to offer assistance to the 18 countries. The schedule was optimistic, given the need to develop plans and obtain agreements with each of the countries, to recruit and train technical staff and to procure and deliver all the necessary supplies and equipment. Surprisingly, these goals were largely achieved, although not without problems.

Discussions in Africa began with the governments concerned immediately after the formal announcement. From 23 November to 17 December, a team composed of Henderson, Dr Clayton Curtis of AID, Dr Henry Gelfand of CDC and Dr Warren Winklestein, a CDC consultant, held meetings with health staff and discussed the programmes with officials of 16 of the 18 countries - at the ministerial meeting of OCCGE countries; at a technical meeting of a counterpart organization for former French colonies in central Africa, OCEAC, comprising Cameroon, Central African Republic, Chad, the Congo and Gabon (the Organisation de Coordination pour la Lutte contre les Endémies en Afrique centrale, or Organization for Coordination in the Control of Endemic Diseases in Central

Africa); and in special visits to Guinea, Liberia, Nigeria, and Sierra Leone. Time constraints precluded visits by the team to the Gambia and Ghana, but government officials there communicated to the respective United States embassies their willingness to participate. Discussions were also held with staff of the WHO Regional Office for Africa attending the OCCGE and OCEAC meetings and by Henderson with the Director-General of WHO and his staff in Geneva.

The only one of the countries noted above for which assistance was not foreseen was the Congo, with which the USA then had no formal diplomatic relations. However, AID agreed to include the Congo, when confronted with the decision by OCEAC leadership that either all or none of its member countries would participate in the regional programme. With this addition, the number of countries increased to 19; when Equatorial Guinea became an independent country in 1968, it too, was included, bringing the number of countries assisted by AID to 20.

The national staff in each country enthusiastically welcomed the proposal for a programme of smallpox eradication and measles control, the latter being the principal attraction to countries in which smallpox was not a significant problem. The inclusion of Nigeria was vital to the success of the programme, since that country accounted in 1965 for nearly three-fourths of all reported smallpox cases and almost half the population of the region. It was most encouraging to learn that a senior health officer in the Nigerian Ministry of Health, Dr G. Adeyemi Ademola, had already elaborated a detailed plan for smallpox eradication which the government had approved and which he was about to dispatch to WHO and AID with a request for assistance.

During the visits in Africa, it became apparent that many United States officials assigned to the countries were not enthusiastic about the programme. As a matter of policy and personal conviction, they attached the highest priority to economic development programmes. Bilateral and multilateral assistance agencies generally considered at that time that improvements in health would follow naturally on economic development and that special programmes in the health sector would serve only to divert resources from the primary objective. Apart from this broader policy issue, the officials concerned anticipated that meeting what were termed

**Memorandum of 10 November 1965**

[Condensed from the original]

Henry M. Gelfand, M.D.

**SUBJECT:** Scope of the Proposed West African AID-CDC Vaccination Program

The principal scientific objectives of the West African vaccination program, as discussed in repeated meetings between ourselves and AID officials have been two: (1) the eradication of smallpox and (2) the control of measles as a significant health problem in the countries under consideration. Since our earliest meetings, it has been noted repeatedly that smallpox eradication was not a realizable goal unless conducted on a comprehensive regional basis.

We have sensed reluctance on the part of AID to include Nigeria and Ghana in the total scheme. The concept that WHO or the United Kingdom might wish to support the Nigerian program in concert with the AID effort in the other countries in this area has been propounded. From knowledge of WHO plans and programs, Dr Henderson can state categorically that it will be difficult for WHO to assign a high level of priority to a Nigerian project for the next few years. Whether the United Kingdom could and would undertake a Nigerian programme reasonably promptly and aggressively is a moot question. The probability that they would, however, is recognizably slight.

It must be reiterated that any multi-country West African smallpox *eradication* program in West Africa must from its inception include Nigeria in its development and planning. Short of so doing, the program is a *control* program only. As stated at the end of August in meetings with AID officials and Dr Karel Raška of WHO, the Communicable Disease Center does not feel that it is indicated nor does it wish to divert skilled personnel to assume full-time responsibility and direction of a program for smallpox and measles in West Africa limited to control only.

The problem of decision and timing with respect to this program is a second major consideration. To recruit capable medical staff ... commitments to them must be made in the fall of the year for employment beginning the following July. This has been firmly and clearly expressed in every meeting conducted with AID officials since early in the summer.

In the proposed program prepared in mid-August it was stated that, "It is important that this PASA [Participating Agency Service Agreement] be negotiated by mid-September 1965, in order that the USPHS may make the necessary staff commitments." We were later informed, however, that October 15 would be more realistic for a firm AID commitment. Postponement of the decision was again requested by AID to November 1 and then November 5. These dates have passed without decision.

In the meantime, a meeting of the Ministers of Health of the OCCGE countries has been scheduled for late November. It was felt by AID and PHS that Dr Henderson and Dr Gelfand should attend to initiate with the attending countries necessary discussions for programs next year. It was agreed, however, that such a trip would be essentially fruitless unless a commitment on the part of AID for full support to a West African program were forthcoming prior to the meeting. Since Dr Henderson and Dr Gelfand would have to depart about November 15, such a decision would have to be reached almost immediately.

Prospects of success for this program are already fading as a firm decision to undertake this activity is deferred. If decisions on the part of AID for full support to the 18-country program cannot be reached by November 15, the Public Health Service would be forced to withdraw such implied commitments as have been made and when AID decisions have been reached, discussions regarding the technical feasibilities would have to be re-explored from the beginning.

"local costs" would present insurmountable difficulties. During the visits of the CDC team the belief was repeatedly emphasized that most countries did not have adequate resources and that AID, as a matter of policy, did not provide for such local costs as the purchase of petrol and vehicle maintenance and repair. This policy had been adopted to ensure that, as far as possible, national governments would cover these recurrent costs by drawing on their own budgets, thereby fostering the continuity of programmes. For many governments, however, the resources available were so severely constrained that many fully equipped and fully staffed projects were unable to function for lack of comparatively small sums of money needed to buy petrol, for example. This potentially serious problem for the smallpox eradication-measles control programme was averted when the Director-General of WHO pledged to make WHO funds available to cover local costs when required. It was a decision about which he was politically uncomfortable since it meant that petrol purchased by WHO would be used to operate vehicles provided by the USA in a bilateral assistance programme. However, he abided by the commitment, and such support was eventually provided to 13 of the countries.

CDC staff had hoped that the overall regional programme could be phased in during a period of 2 years, some countries beginning operations in 1967 but as many as possible delaying them until 1968 to permit the necessary planning. For various reasons, however, such a delay was possible only in Guinea, Liberia and Sierra Leone. A programme in Nigeria was essential from the beginning of the regional effort, because of the size of the country and the fact that its central location made it the most logical site for the programme's regional office. Programmes had also perforce to be introduced in 1967 in the OCCGE and OCEAC countries because of commitments already made by AID for measles vaccination campaigns. Because of these and other political considerations, it was decided that programmes would have to begin in 1967 in 16 countries and in 1968 in the other 3.

The direction of the regional programme at CDC was yet another problem. A Smallpox Unit had been created in the CDC Surveillance Section in 1962 which, under the direction of Dr J. Donald Millar, had ably conducted studies on the use of the jet injector for smallpox vaccination and on the fre-

quency of complications following vaccination. It was logical that he should assume direction of the regional programme but, in August 1965, he departed for a year's post-graduate study. In December 1965, with Dr Millar temporarily absent and no other suitable leadership available, Henderson relinquished his post as chief of the Surveillance Section to assume direction of the programme until Dr Millar returned. He was joined by his deputy, Mr Leo Morris, as well as by Dr Bernard Challenor, Dr Gelfand and Dr Ralph Henderson, and an administrative officer, Mr Billy Griggs—all CDC staff.

Within a month of the initial discussions with African health leaders, a 60-page document had been prepared which specified objectives and activities and identified needs and costs for personnel and commodities by country (Table 17.2). With minor modifications, this compilation was accepted by AID. The total cost of United States assistance was estimated to average about US\$7 million per annum, of which approximately 40% was associated with the measles vaccination component, including storage refrigerators and jet injectors. It was anticipated that, on average, an additional US\$1.7 million would be needed annually from WHO for local costs, a figure which, if correct, would have required 70% of all the WHO regular budget funds subsequently appropriated for smallpox eradication. Fortunately, the countries themselves eventually bore most of these local costs—WHO providing US\$1.1 million to 13 countries from 1967 to 1972, or about US\$200 000 per annum.

The projected size of the staff in the programme's regional office in Lagos and the central office in Atlanta, comprising about one-third of the total personnel, requires comment, as it was considered by some to be excessive and was accepted only with reluctance. The requirements, as outlined, arose from observations of other field programmes by CDC staff. It was believed that such programmes had regularly underestimated the need for central support and, indeed, this proved to be WHO's experience in establishing the Intensified Smallpox Eradication Programme. The regional office in Lagos was expected to exercise broadly delegated responsibilities for administration and field supervision. The personnel concerned were expected to travel extensively to effect coordination and to provide short-term emergency technical support, as well as to assist the Lagos

<sup>b</sup> Expected to be met mainly by WHO.

laboratory in the development of vaccine production. The document proposed the recruitment of 2 medical officers, 2 administrative officers, an equipment specialist, a health educator and a virologist. The CDC staff in Atlanta would be responsible for liaison with AID staff in Washington and with other agencies, for the recruitment and training of staff, for the development of instructional manuals, for the procurement and shipment of supplies and equipment, for the provision of longer-term emergency assistance in problem areas, and for the conduct of special studies pertaining to the programme. Although practical realities eventually required a redefinition of the respective roles of the two offices, experience demonstrated that the proportionately large staff in the central and regional offices, and the flexibility in assigning personnel which this implied, were vital to the rapid progress ultimately achieved.

In the programme document, the primary goal was specifically stated to be the eradication of smallpox, with measles control as a secondary objective, but longer-term objectives were envisaged:

- "1. The establishment or, in some countries, improvement of mobile disease control services capable of administering vaccines or other preventive medications efficiently, economically and on a mass scale throughout the country.
- "2. The establishment in each country of a system of disease surveillance broadly applicable to a variety of communicable disease problems.

"3. The development of highly simplified statistical sampling techniques applicable in these developing countries which will permit rapid assessment of disease problems.

"4. The establishment of elementary virological laboratories ... for the diagnosis of smallpox. [This objective was soon abandoned, as it was in other areas, when it became clear that the clinical diagnosis of smallpox was usually sufficiently accurate for surveillance purposes, and when it was discovered that laboratory diagnosis by the more sophisticated electron microscopy offered substantial advantages over traditional methods.]

"5. Improvement of the existing smallpox vaccine production laboratory in Nigeria such that it [can produce] vaccine of the multiple puncture type in quantities sufficient for Nigeria and other countries in the area."

### PREPARATION FOR THE CAMPAIGN, JANUARY-DECEMBER 1966

As might be expected in the development of a new programme of this magnitude, the preparatory phase, during January-December 1966, was characterized by hectic activity and administrative frustration. A director for the CDC regional office to be established in Lagos, Dr George Lythcott, was recruited early in 1966. He, with Dr Gelfand and Dr Ralph Henderson, travelled throughout western and central Africa drawing up pro-

gramme agreements for each country. Such agreements, however, could not be formally signed nor could the procurement of supplies and equipment begin until the United States Congress had passed the act which appropriated the funds. Although this had been expected before 1 July, when the government's fiscal year began, the Foreign Assistance Act of 1966 was not signed until 19 September. The difficulties in launching the programme were compounded by the fact that, within AID, the interval between the decision to implement field programmes and their actual commencement was usually 3 years, and the Agency's procedures were geared to this pace. As time progressed, it became apparent that the single year allotted for preparation was unrealistic unless special measures were taken.

Fortunately, the recruitment of staff had been authorized and training could begin early in July 1966. Two basic categories of staff were recruited: medical officer-epidemiologists to provide overall assistance in programme development and execution, and non-medical personnel, termed "operations officers", who would deal with logistics—including the maintenance and repair of vehicles and jet injectors, the distribution of supplies and equipment and the handling of financial matters. Priority was given to persons in their twenties and thirties, who were considered to be more likely than older individuals to have the stamina and interest required for extended work in the field. This also reflected the view of African health officials, who argued that they had a very limited need for advisers, in the usual sense of the term, but required, instead, individuals who were willing to participate actively in field operations. One operations officer was recruited for each country and 1 for each of the 4 regions in Nigeria. One medical officer was recruited for each Nigerian region, 1 for each of the larger countries, and 1 for every 2 or 3 of the smaller countries—i.e., 1 for Dahomey and Togo, 1 for Cameroon and Gabon, 1 for Chad and the Central African Republic, and 1 for the Gambia, Mauritania and Senegal.

The medical officers were primarily epidemiologists who had worked in the USA with CDC or who had had international health experience. The operations officers included 4 with experience as United States Peace Corps volunteers, the rest having played an important role in CDC's domestic disease control

programmes. The latter group, all of whom were university graduates, had received short-term training in epidemiology and disease control and had proved their merit in field control programmes. Their experience in programme management and field investigations was to prove invaluable. Although the operations officers were initially not well accepted by some senior government health staff because they lacked a medical degree, they rapidly earned respect and, in many areas, eventually served as senior advisers. So impressive was their performance that WHO increasingly recruited such persons for small-pox eradication and other programmes.

During the spring and summer of 1966, a manual for field operations was prepared from which the WHO *Handbook for Smallpox Eradication in Endemic Areas* (SE/67.5 Rev.1) was eventually adapted; other manuals dealing with the repair and maintenance of the jet injectors were prepared and tested in the field by Mr Morris; and orders were drawn up for the procurement of the necessary supplies and equipment.

Numerous problems were resolved during this period but a few of the more important and unexpected deserve mention. The licensing of smallpox vaccine for use in the jet injector caused one, wholly unexpected difficulty. CDC staff had assumed that the inoculation of vaccinia virus into the superficial layers of the skin by the jet injector's high-pressure spray achieved the same result as the administration of the vaccine by the scratch of a needle. However, in 1966, the agency in the USA responsible for biologicals—the Division of Biologics Standards—asserted that the vaccine specially produced for the jet injector had to be treated as a new product and because it was intended for parenteral inoculation, it must be sterile. Vaccinia virus, however, was then being grown as it always had been on the flank of a calf, and when harvested it inevitably contained some bacteria. Subsequent steps in manufacture diminished the number of bacteria to very low levels, and tests were performed to ensure the absence of pathogenic species. It was impossible, however, to produce a vaccine which could be stated with certainty to be free of all bacteria unless it were grown in tissue culture. Vaccinia virus could be grown in tissue culture, but at that time no laboratory had succeeded in producing such a vaccine which met WHO's heat-stability requirements. The debate as to whether the vaccine for jet injection

had to be sterile spread from the USA to WHO, where those concerned with biological standards also proposed that vaccine intended for jet injection should be sterile. Although there was agreement that the issue was one of principle rather than perceived risk, those concerned with biological standards insisted that principle should take precedence over all other considerations. Faced with the prospect of having a thoroughly evaluated method for vaccination which was vital to the new programme, but no vaccine, CDC staff carried the debate to higher administrative levels within the United States Public Health Service and the World Health Organization and finally were able to gain agreement that, in this case, principle would not prevail. However, considerable time and effort were spent on resolving the problem—at the expense of other urgent activities.

The vehicles and their spare parts presented a second problem. CDC decided that standard model pick-up trucks rather than custom-designed vehicles were preferable and less costly, and that the refrigerators required for the transport of measles vaccine could simply be bolted to the bed of the truck. The most desirable were British or French vehicles, which were in common use throughout western and central Africa. Spare parts for such vehicles were already widely available and local mechanics were familiar with their necessary maintenance and repair. AID procurement policies, however, required the purchase of vehicles made in the USA, and efforts by CDC to obtain a waiver of this requirement were unsuccessful. To alleviate the problems of repair, arrangements were made with the manufacturer for all of the programme's professional staff to take intensive training in vehicle maintenance and repair. Spare parts had to be procured and specially stockpiled in all countries, but which spare parts and in what quantities was another question, since, curiously, neither the manufacturer nor the various agencies working in Africa, including WHO and UNICEF, had compiled a list of needed spare parts based on field experience. There was no option but to make a "best-guess" estimate of which spare parts to stock and, as might be expected, requirements only roughly approximated available stocks. Over time, and with special assistance from the manufacturers, the design of the vehicles was improved, special repair facilities were established and an effective transport system was ensured.

One of the most contentious problems related to the question of which of two measles vaccines should be procured—the Edmonston strain vaccine, which was produced by one manufacturer and which had been used since the 1961 campaign in Upper Volta, or a more recently licensed, more attenuated product, the Schwarz strain vaccine, produced by another manufacturer. The Schwarz strain vaccine resulted in less frequent and less marked febrile responses, but the initial antibody levels induced were lower (Krugman et al., 1965). The available evidence indicated that the two vaccines conferred comparable immunity but some investigators suggested that immunity following the use of the Schwarz vaccine might not be so long-lasting. Investigators in Senegal and Nigeria (Hendrickse et al., 1965) had evaluated the Schwarz strain vaccine and argued that it was the more desirable, given the fact that it would be administered to ill and malnourished children among whom the higher fevers caused by the Edmonston strain vaccine might be harmful. A number of African countries, however, encouraged by the manufacturer's travelling sales representative, requested the Edmonston strain vaccine. Even the *New England journal of medicine* (1965) entered the dispute, stating in an editorial, "... it may be wise, at least under circumstances such as exist in these countries [of western Africa], not to adopt other vaccines [other than the Edmonston strain vaccine] until the results of future studies become available". The manufacturer translated the editorial into French and circulated it widely in Africa, and eventually obtained support for the product from many United States legislators. One alternative for CDC was to permit each country to decide for itself which strain of vaccine would be used. However, CDC staff not only considered the Schwarz strain to be preferable, but for logistic reasons believed it important to employ only one type of vaccine. Eventually, the issue was decided by the United States Surgeon General, and ultimately all countries were persuaded to accept the use of this strain (which became routinely used). As with the standards for smallpox vaccine for use in the jet injector, the issue was satisfactorily resolved, but again at the expense of considerable time and energy.

The training programme began in July 1966. A month-long course in basic field epidemiology and biostatistics was followed by a month of specialized training which

covered subjects ranging from the history and socio-cultural characteristics of western and central Africa to the maintenance and repair of vehicles and jet injectors. To foster collaboration with WHO, the WHO advisers in Africa, Ladnyi and Dr Hans Mayer, were invited to participate during the first month of the course. When the course ended, however, the staff had to remain in Atlanta, housed in temporary and crowded quarters, because none of the national agreements had yet been signed.

Many discussions with governments about the programme had been conducted during the spring and summer of 1966 but, as has been noted earlier, formal agreements could not be signed at least until September. Nigeria was of the highest priority because of its size and because it was to serve as the site of the regional office. Nearly half the complement of technical staff were expected to live there.

Nigeria, however, was then on the brink of civil war. A military *coup* in January 1966 had displaced the existing civilian authority, and 7 months later, a second *coup* coincided with an army mutiny in the north, during which thousands of Ibo tribesmen were killed. The Ibos, whose tribal home was eastern Nigeria, threatened to secede and to establish an independent nation. The signing of an agreement for a smallpox eradication measles control programme was not high on the list of the government's priorities. For many weeks, it appeared that the regional programme might well be doomed, as the United States Ambassador and the WHO Representative endeavoured, unsuccessfully, to obtain the agreement of the Nigerian government. Finally, Dr Lythcott flew to Nigeria to ascertain what might be done. The documents had been approved by the Minister of Health and awaited only the signature of the head of state.

**Plate 17.4.** CDC field staff received training in the maintenance and repair of vehicles in Atlanta before taking up assignments in western and central Africa. Clockwise from lower left: Margaret E. Grigsby, Ralph H. Henderson, Gordon E. Robbins, a vehicle maintenance instructor, Stanley O. Foster, Thomas Drake, E. Ademola Smith, William H. Foegel, David Thompson, Donald Moore, Deane L. Hutchins, Hillard Davis, unidentified, Arlen Rosenbloom, Pascal Imperato, Bernard Lourie, Christopher D'Amanda.

During a 6-week period, Dr Lythcott, too, was unsuccessful in working through conventional channels but, at a social function, he was introduced to the President's fiancée. He explained the programme and the nature of his mission to her, and on the following day, the agreement was signed.

Nigeria's agreement, though it was crucial, was only one of 16 which were needed. In other countries, various problems delayed the signing of the programme agreements, and not until March 1967 was the last of these finalized. Agreement in principle to undertake a programme of smallpox eradication and measles control was more readily achieved than agreement on specific operational plans. CDC staff had envisaged a similar type of programme in all countries—in principle, an elaboration of the special mass vaccination campaign against measles. Mobile teams would use jet injectors in the administration of smallpox vaccination to everyone in the population, while measles vaccine would be given to children between 6 months and 4 years of age (Henderson, 1967). Expectations as to the extent of coverage to be achieved were modest—80% of the population in urban areas and perhaps 60% in peripheral areas. Important additional components, not then familiar to any of the countries, were the provision of independent assessment as a quality control measure to determine vaccine coverage and the success of vaccination, as well as a surveillance system utilizing detection sites such as hospitals and aid posts to measure progress in eliminating smallpox.

In countries in which mobile teams had previously been little used, or in which such teams had largely ceased to function, the plan was adopted with few changes. In most of the former French colonies, however, multi-purpose mobile prevention units, often referred to as "prospection teams", were well established. As the teams moved from village to village on a planned itinerary they endeavoured to reach all parts of a country over a 2–3 year period, vaccinating the inhabitants against smallpox and sometimes tuberculosis and yellow fever and examining an average of 400–500 persons a day for leprosy, trypanosomiasis, yaws and (where the disease was present) onchocerciasis. The programmes, as well as many of the mobile units, were usually directed by French military medical officers. In these countries, separate programmes for smallpox and measles vaccination were seen

WHO/CHEVAIFR

**Plate 17.5.** Jet injectors were used to administer smallpox vaccine in the left arm and measles vaccine in the right arm. Sometimes the injections were given simultaneously. Aluminium foil covers the vaccine vials to prevent the inactivation of virus by exposure to light.

to be wasteful of petrol and trained personnel. CDC staff, however, considered that the integration of the two programmes would present a problem because it would compromise the speed and efficiency of operations afforded by the jet injectors. In a population of 500, for example, fewer than 100 children would be of a suitable age to receive measles vaccine, a number barely sufficient to warrant the use of the injectors. A second problem was that the health officials in these countries saw no need to provide special teams to assess the results of the programme. Participation in the multi-purpose programmes was encouraged in most countries by giving individual certificates to persons examined and vaccinated by the teams, and by subsequently requiring these documents to be shown for administrative purposes. Because the prospection teams were well known to the people, and their activities were supported by local chiefs, health officials believed that no assessment was required other than to compare the numbers vaccinated by the teams with the estimated population in the area. A third problem was the reluctance of most authori-

ties to divert resources to improve reporting or to investigate cases of smallpox. This was considered to be wasteful because of the common view that the best that could be achieved was the control of smallpox as well as of measles; if a few cases of smallpox did occur they were thought of little consequence in the total context of health problems.

Compromises in the basic strategy were required. Support from the Secretaries-General of OCCGE and OCEAC—Médécin-Général Pierre Richet and Colonel René Labusquière, respectively—helped to resolve many problems. In the OCEAC countries, the smallpox eradication and measles control programmes were eventually fully integrated into the activities of the prospection teams (see box). In Upper Volta, the prospection teams continued to give smallpox vaccine but different mobile teams were created to give measles vaccine. In Côte d'Ivoire, separate

measles vaccination teams and smallpox vaccination teams were formed (Table 17.3). In the other OCCGE countries, it was decided that special teams would conduct both smallpox and measles vaccination.

Few of the countries at first agreed to accept the provision of special teams to conduct independent assessments of smallpox vaccination coverage and takes. By the end of 1967, only 6 countries had created such teams—Dahomey, Ghana, Mali, Niger, Nigeria and Togo—although eventually 4 others did so—Chad, Gambia, Guinea and Sierra Leone. At the start, there was even less interest in smallpox surveillance, which fell by default to CDC advisers until late in 1968. Fortunately, assessment and surveillance were best accepted in the countries in which smallpox was the greatest problem.

When the first programme plan had been developed, in January 1966, it had been

#### Description of a Prospection Team in Action, Central African Republic

From a 1967 field report by Dr Ralph Henderson and Mr Neal Ewan:

"The team began its activities around 7.30 a.m. Zinga and an adjoining village were to be 'prospected' that morning. First, all the children between 6 months and 4 years of age were formed into a line and given measles vaccinations. They were tallied by age and sex as they received their shots. This procedure required about one-half hour, and took place with minimal difficulty.

"The team leader then requested the village to form into a line of males and a line of females. Each line then passed in front of a recorder, who tallied age and sex, and handed each person a metal tag from a box containing tags consecutively numbered from 1 to 1000. The line then moved through a small tent where a nurse performed a screening physical examination, particularly looking for trypanosomiasis, onchocerciasis, leprosy, and yaws. After passing through the tent, the line passed in front of the smallpox vaccination station, where everyone except infants under 3 months and pregnant women was vaccinated using the scratch technique. The line next moved to a table where each metal tag was collected, and yellow OCEAC cloth health certificates were given out, stamped with *rougeole* (measles) and/or *variole* (smallpox) and the date, and filled out with the person's name. People were then either dismissed or proceeded to one or more of three additional sites. Blood, sputum and stool specimens were obtained from suspects referred by the nurse performing screening physicals. The nurse concerned prepared slides to be read by one of two microscopists. Trypanosomiasis and onchocerciasis suspects were referred directly to the microscopists, who made their own slides from fluid and tissue obtained by placing a clean needle into suspected cysts or ganglions and wiggling it.

"The final member of the team dispensed drugs. Patients were either referred from the nurse doing screening physicals, or were passed along by the microscopists. Penicillin shots were given to yaws cases and their contacts. Chloroquine, aspirin and some antifungal skin ointments comprised the remainder of the basic pharmacy. Those with other diagnosed illness were referred to a local hospital or dispensary for treatment. By 11 a.m., about 250 people had been seen in this fashion, and the team packed up to move to the village where they would prospect on the following day."

projected that "smallpox cases should cease by the end of the fourth year of the programme" i.e., by December 1970. In the autumn of 1966, projections were made as to the numbers of reported cases of smallpox which might be expected up to the end of the programme. This was done in the expectation that, with better recording, the reported incidence might actually rise during the first year of operations, thus generating concern on the part of the responsible administrators as to the effectiveness of the programme. Anticipating this problem, Henderson and his colleagues prepared a graph depicting the expected numbers of reported cases throughout the duration of the programme (Fig. 17.2). The graph is of interest, since the predicted incidence up to the end of 1968 was surprisingly close to what was actually found, but thereafter the results were substantially better than expected, one of the few occasions in which progress in the Intensified Smallpox Eradication Programme exceeded expectations.

One by one the programme agreements were signed, and personnel, supplies and equipment gradually began to arrive in western and central Africa. By March 1967, 16 months after the USA's decision to offer assistance, pilot projects had begun in 11 of the countries and a total of 2.5 million smallpox vaccinations had been recorded.

### CHARACTERISTICS OF WESTERN AND CENTRAL AFRICA

The estimated 110 million population of the 19 countries included in the programme in 1967 inhabited a diverse ecological area ranging from humid tropical coastal areas with prolonged rainy seasons to rolling savanna and eventually to the vast, sparsely populated and arid Sahel, whose vegetation consisted of thorny scrub and stunted trees (Plate 17.6). Subsistence farmers formed the largest proportion of the population. Chris-

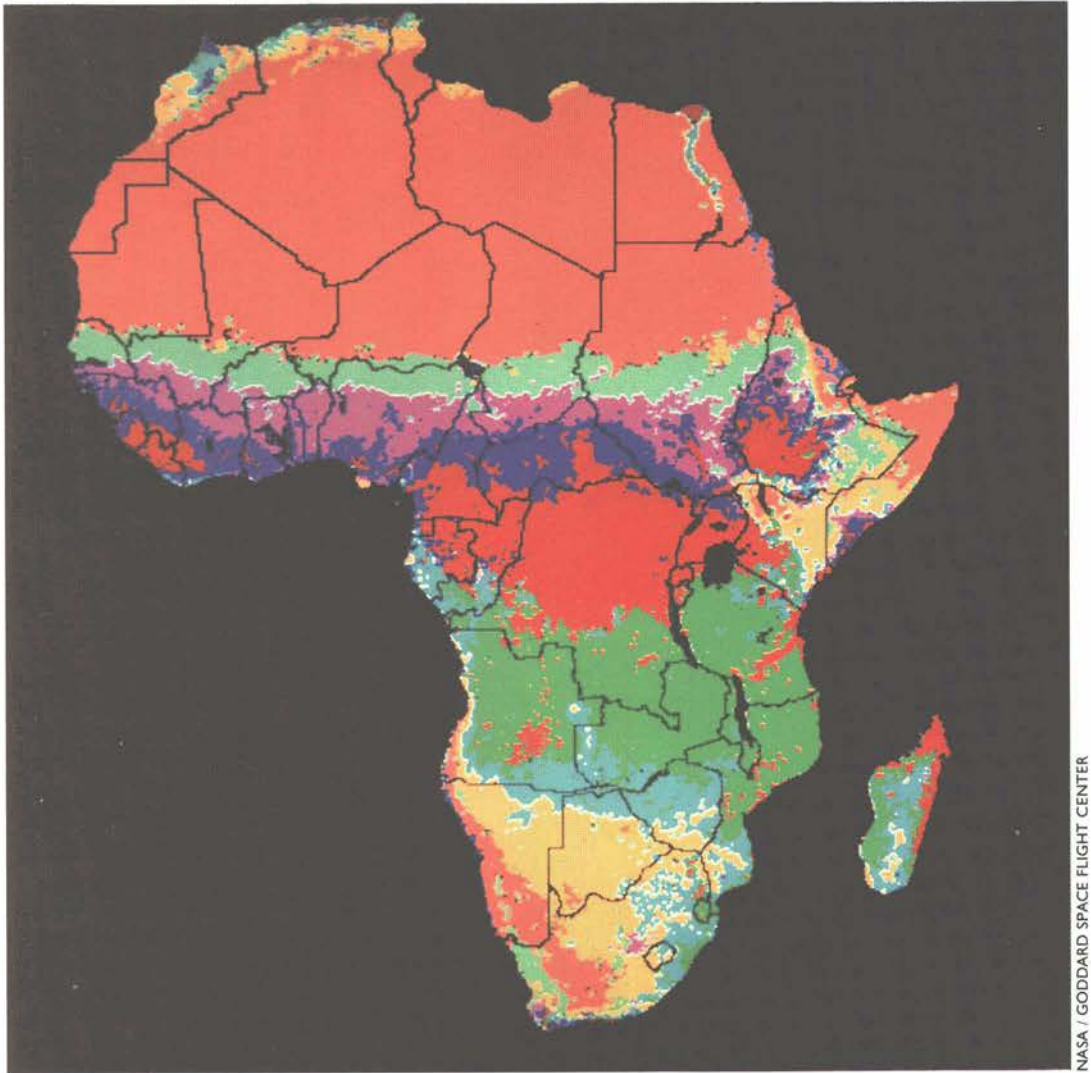

Fig. 17.2. Western and central Africa: number of reported cases of smallpox compared with the numbers predicted in September 1966.

**Plate 17.6.** Principal land cover components of Africa. The types of vegetation present in different parts of Africa were important in population distribution. Maps developed from satellite observations using very high-resolution radiometer sensors were prepared in 1982 (Tucker et al., 1985); the situation they show was probably not significantly different from that in 1967. The tan areas are desert and semi-desert, the light green are semi-arid wooded grassland, and the light blue are bushland and thicket; all these areas were sparsely populated. The purple areas are woodland and grassland, the dark green are woodland and the yellow are wooded grassland and thicket. The dark blue areas are interspersed tropical forest and grassland, and the red are tropical rain forest and mountain forest; the latter areas were more densely populated.

tians and animists lived primarily in the coastal areas; Muslim herders inhabited the Sahel. Tribes numbering from less than 100 000 persons to many millions, each with its own language, culture and customs, had traditional boundaries, often overlapping one or more national frontiers. In the process of evolving into nation-states, most countries experienced clashes between the new and the established and between religious, traditional, military and civilian leaders. Changes of government occurred frequently.

Paved roads provided limited links between coastal cities and some inland towns, but few connected the major capital cities. In the savanna, most unpaved roads were made of laterite, with a washboard surface that took a heavy toll of vehicles; in the coastal areas, there were clay roads, which were dusty during the dry season and a morass of mud during the rains. Railways were few and frequently out of order. Air transport connected many of the major cities and towns but schedules were followed erratically. Travel between one capital and another was sometimes more readily accomplished by flying by way of London or Paris. Similarly, telephone and telegraph links were generally few, and it was often easier to communicate with other countries through London or Paris.

The inhabitants of western and central Africa were inveterate traders and, despite poor roads, many travelled long distances to buy and sell cattle, textiles, salt, gold and other products. Local markets played an important role in commerce and as social centres. Some were held weekly, others at intervals of 4, 5 or 8 days. Herdsmen moved regularly across the Sahel seeking grazing areas and migrant labourers from the Sahel moved seasonally to coastal and savanna areas to harvest crops. Rapidly increasing urbanization characterized the entire area, the population of Abidjan (Côte d'Ivoire), for example, growing from 5000 in 1921 to 180 000 in 1966 and the population of Lagos (Nigeria) from 100 000 to 665 000 during the same period.

National administrative structures largely reflected the legacy of the previous British and French colonial administrations. In the former British colonies, the authority of the tribal chiefs had been supported and fostered within a decentralized civil structure; in the former French colonies, however, the power of the traditional chiefs was largely subordinated to that of the civil service and a strong centralized government. For the smallpox

eradication-measles control programme, the support of the principal chiefs in the former British colonies was therefore as vital as that of the civil authorities; in the former French colonies, the civil service and village leaders provided the essential link with the people. The governmental structure was different in Guinea and Mali, where the authority of a national political party superseded that of traditional leaders. In both countries, the parties greatly facilitated contact with the villagers.

Approaches to the provision of health services also differed, depending on the colonial tradition. In the former British colonies, rural dispensaries operated by African personnel provided basic drugs and sometimes vaccine, but they were rather few and far between and their efforts were devoted primarily to curative medicine. The establishment of mission clinics and hospitals was encouraged, however, and in some areas these were quite numerous. In the former colonies of France, in contrast, health services were more widely available, through the use of mobile multi-purpose prospection teams. The system, conceived during the 1920s by Dr Eugène Jamot, had first been used to control trypanosomiasis in Ubangui-Shari (later the Central African Republic), but the teams' duties were gradually expanded to include the prevention and treatment of other diseases; in time, similar teams were organized throughout French West Africa and French Equatorial Africa (Richet, 1965; Cohen, 1971). The Service des Grandes Endémies, as the mobile service was called, provided basic health services in rural areas, supported by dispensaries, which served as treatment centres for patients referred by the mobile teams. The establishment of mission clinics and hospitals had not been encouraged and therefore not many existed. After the colonial period, health services continued to be supported in most countries by French bilateral assistance. Mobile teams were also used in some of the former British colonies for yaws control and occasionally for smallpox vaccination, but, except in Ghana (Waddy, 1956), they did not operate throughout the entire country.

Thus, in a number of the countries of western and central Africa, a structure and/or tradition existed for executing large-scale vaccination campaigns. Systems for the notification and investigation of cases, however, were poorly developed.

## PLANS FOR THE PROGRAMME

With only 13 months allotted before the commencement of field operations, and with available personnel fully committed to working out the logistics, CDC staff had had no time to undertake feasibility studies, pilot projects or field reconnaissance to determine the extent of vaccinia immunity or to assess the epidemiology of smallpox or measles. A number of assumptions were made, some of which were later to prove erroneous. For example, it was assumed that vaccinia immunity was uniformly low throughout the region but, in fact, urban populations were later found to have been moderately well vaccinated, as were the inhabitants of large rural areas in some francophone countries. Especially low levels of vaccinia immunity were observed, however, throughout northern Nigeria, in many parts of Sierra Leone and in the more isolated rural villages in most countries. It was also believed that cases of smallpox would be found to be widely dispersed in all countries but, in fact, 10 out of the 21 countries in the region were found to be free of smallpox or nearly so by 1967. Where smallpox incidence was high, cases and outbreaks tended to be concentrated in specific geographical areas. It was also assumed that, as in Asia, the densely populated cities and market towns would constitute the major reservoir for the sustained transmission of disease, with spread occurring from these foci to rural areas (Henderson, 1967). It was discovered, however, that comparatively few cases occurred in urban areas but rural areas were found to be capable of sustaining transmission over surprisingly long periods.

CDC staff viewed the eradication of smallpox as a feasible objective given its epidemiological characteristics, but less was known about measles, since it was not routinely reported in most countries. However, control rather than eradication was foreseen because of the greater communicability of measles, especially in Africa (Morley, 1962; Senecal et al., 1962), the greater difficulty of clinical diagnosis and the fact that the disease had not been eliminated in any country, as of 1967, even in those with well-developed health services. Whether the objective of the programme should be defined in terms of the control of measles or its eradication had been debated at length. AID staff thought it preferable to establish eradication as an objective, believing that even if it was not achieved,

more substantial progress would be made. CDC staff were concerned lest the enunciation of a goal which might prove to be unrealistic, as had been the case with malaria eradication (see Chapter 9), would only serve to erode further the credibility of public health professionals. Eventually, the CDC position prevailed and so the programme bore the somewhat clumsy title of "smallpox eradication-measles control" rather than the simpler "smallpox and measles eradication." As the programme was to demonstrate, effective measles control, let alone eradication, was a formidable task (United States National Communicable Disease Center, 1970; Foege & Eddins, 1973).

The planning process would unquestionably have benefited if more information had been available regarding the incidence of both smallpox and measles and the capacities of each of the national health services, but the seeking of such information would have caused a delay of perhaps 12-18 months. With many commitments already made, so long a delay was not acceptable. Moreover, because of possible changes of government staff and of priorities, there was no guarantee that a better-defined project would subsequently be approved for funding. Thus, with the resources at hand, there was a need to act. Consequently, the project began without preparatory studies, employing such information as was available; a great many assumptions were made in the hope that an able and energetic staff would solve problems as they arose.

It was recognized that the different characteristics of the administrative, health and social structures in each of the countries would dictate somewhat different types of programme. Therefore, instead of a highly prescriptive plan, four principles were formulated for the execution of the national programmes in the expectation that during the first year they would evolve by trial and error: (1) the programmes would be coordinated as a regional effort because of the ready movement of people across national borders; (2) freeze-dried vaccine would be administered by mobile teams employing jet injectors in order to economize on scarce resources; (3) independent assessment of the vaccination campaign would provide a quality control mechanism; (4) a workable surveillance programme would be developed on the basis of regular reporting from case-detection sites, because, as had been stated, "The goal of the

project is a specific one, the reduction of smallpox to the level of zero cases" (Henderson, 1967).

Surveillance, as a principle, was a characteristic which differentiated this from previous smallpox eradication programmes and eventually proved to be critical to its success. It was a concept that had been fostered by Dr A. D. Langmuir at CDC (see Chapter 9); since 1961, CDC's surveillance programme had been under Henderson's direction. With respect to smallpox, it was defined in the following terms (United States Communicable Disease Center, 1966):

(1) The routine, systematic collection of data, amplified appropriately by special field investigations and studies.

(2) The analysis and interpretation of reported data and studies on a concurrent basis.

(3) The initiation of appropriate definitive action, including field investigation, epidemic control, modification of operational campaign procedures, and recommendations regarding vaccination.

(4) Widespread dissemination of the compiled and interpreted data to principal reporting sources and to others concerned with disease control activities.

As has been noted earlier, the concept of surveillance was unfamiliar to health staff in western and central Africa and it was thought that not less than 2 years of sustained effort would be required to develop a surveillance system. The CDC *Manual of Operations* (United States Communicable Disease Center, 1966) pointed out the need to begin the development of a notification system from the inception of the programme but did not then envisage the obligation to investigate and contain all the outbreaks that were detected. As the manual stated:

"In countries with a high endemic occurrence of disease, field investigation activities may focus on comparatively few of the many outbreaks. As systematic vaccination programs progress, the importance of small outbreaks and individual cases becomes increasingly important. As the numbers of cases diminish, the field investigation and control procedures should be instigated for an increasing proportion and, ultimately, for all cases."

Three stages in the development of the surveillance programme were envisaged:

**PHASE I** Referring to endemic areas with a sustained or frequent high incidence of

smallpox as indicated either by official reports or by educated estimates. This would include all countries with a rate of perhaps 1 or 2 cases or more per 100 000 population per year.

**PHASE II**—Referring to countries with a low continuing incidence of smallpox.

**PHASE III**—Referring to areas rendered non-endemic by systematic vaccination. No country or subdivision would be classified in Phase III until it had been covered by the attack phase of systematic mass vaccination.

Strategically, surveillance and containment activities in most countries were initially considered as subsidiary to mass vaccination, serving primarily to identify problems or weaknesses in the mass vaccination campaign. When the number of cases had been substantially reduced by the vaccination campaign, surveillance and containment would become essential to eliminate residual foci. The activities deemed appropriate for each phase of the programme are listed in Table 17.4. On the basis of the reported incidence in 1966, Phase I activities were called for in at least 6 of the countries—Dahomey, Mali, Niger, Nigeria, Sierra Leone and Togo.

## EXECUTION OF THE PROGRAMME

The first year of the programme was to be devoted to formulating logistic plans, training national staff, and evaluating methodologies for adaptation by both national and CDC personnel. Although it was inevitable that the development of a programme of this magnitude would encounter substantial problems, their extent had not been anticipated. The solution of these problems by CDC ultimately became the responsibility of Dr Millar, who returned from study leave in the summer of 1966 and assumed direction of the programme on 1 November, when Henderson went to Geneva to head WHO's Intensified Smallpox Eradication Programme.

By September 1966, the recruitment and training of staff had been completed as scheduled, but little else was proceeding as planned. The procurement of supplies and equipment lagged far behind schedule and formal agreements with countries were slow to be concluded. Two countries refused to sign programme agreements until they had been formally assured that WHO would provide funds for fuel supplies and travel;

Table 17.4. Western and central Africa: surveillance activities at different phases of the programme<sup>a</sup>

	Phase I	Phase II	Phase III
Reporting	Emphasis on principal medical units to obtain regular reports. Progressive extension to include all medical and paramedical units.	Extension of surveillance network to ensure that detection sites exist in all parts of country and that reports are regularly submitted. Some telegraphic reporting of cases.	As in Phase II. All cases reported telegraphically.
Field investigation	Investigation of significant epidemics or epidemics in unusual areas as time permits.	All outbreaks promptly investigated by competent epidemiological authority. Cases promptly investigated by national or intermediate health jurisdictions. Case investigation forms submitted for every case.	Each case an "emergency". All cases promptly and routinely investigated by competent epidemiological authority.
Control procedures	Special units to undertake epidemic control as necessary.	Prompt control procedures for each case and outbreak by central or intermediate health authority.	Prompt control procedures with central authority participation. Identification, vaccination and, if necessary, isolation of contacts.
Laboratory study of cases	Only in special circumstances, usually for research purposes.	Specimens to be obtained from each isolated case and representative samples from outbreaks.	Every case to receive laboratory study.

<sup>a</sup> From United States Communicable Disease Center (1966).

several objected to the requirements for surveillance; another expressed concern about budgetary obligations; in Upper Volta, in which the measles control programme had first been successfully conducted, the director of the endemic diseases control service refused to endorse the programme on the grounds that smallpox eradication could not be

achieved. Continuing discussions eventually led to the signing of 3 agreements in October, 4 in November and 3 in December. The last to be signed were those in the Gambia, Senegal and Upper Volta, in March 1967.

Each national programme experienced different types of problems and each had to be adapted to the health structure and social

context of the country concerned. As programmes progressed, epidemiological observations and useful techniques for field operations were communicated from one to another through annual meetings of national directors and CDC advisers, through the travel of staff based in Lagos and Atlanta and through periodic surveillance reports which were sent to programme staff in all countries. To attempt to present events throughout the region in chronological order is difficult and confusing, given the number of different national programmes. Accordingly, we shall first describe progress in the programme as a whole before commenting on the salient features of individual national programmes.

In most of the countries, field operations commenced between January and June 1967; in the others, for which assistance had been postponed for a year—Guinea, Liberia and Sierra Leone—these operations had all begun by January 1968.

The proposed method of operation in each of the vaccination campaigns drew extensively on the experience of Dr Harald Frederiksen, a United States adviser to an earlier successful smallpox vaccination campaign in Bolivia (Frederiksen, 1962). It called for vaccination of the population at assembly points. This was achieved through preparatory meetings with local chiefs and civil authorities to explain the programme and to solicit their help. Such meetings took place 1 to 7 days before the vaccination team arrived. The assembly points were usually selected so that no one would have to walk more than 8 kilometres, although, in some areas, even this distance was found to be too great and it was decreased to 3 kilometres. The teams usually consisted of 5 or 6 persons—as many as could conveniently ride in one vehicle. They vaccinated all persons against smallpox and children between 6 months and 4 years old against measles. Although on some days as many as 10 000–14 000 persons could be vaccinated, on average the teams administered between 750 and 3000 smallpox vaccination daily (Millar & Foege, 1969) and about one-fifth of this number of measles vaccinations. The teams usually worked for a consecutive 3-week period, camping out or staying in the villages. As experience demonstrated, living among the local population fostered cooperation and improved vaccination coverage. At the end of the 3 weeks, 7–10 days were set aside for rest and recuperation.

Jet injectors were used for most vaccinations, but in small villages and among special groups, smallpox vaccine was administered by bifurcated needle. Most people readily accepted vaccination, although resistance was encountered in Dahomey, Togo and south-western Nigeria, where an animist cult was active among some small groups, and in scattered, remote areas. In each instance, special efforts were made to persuade village and religious leaders of the benefits of vaccination—usually, but not always, with success.

In urban settings, the vaccination campaign required special planning and the provision of many more vaccination assembly points. In Nigerian towns, it was calculated that one assembly point would be required for every 8000 persons and that arrangements would have to be made for vaccination in the early morning and late afternoon (Smith et al., 1970). The most intensive urban campaign was that conducted in Ibadan (Nigeria), in which, over a 10-day period, 12 teams administered 757 308 smallpox vaccinations and 69 069 measles vaccinations. People connected with the university, local churches and private voluntary organizations, as well as members of the police force, assisted in the effort.

CENTERS FOR DISEASE CONTROL

**Plate 17.8.** William Stewart, Surgeon General of the United States Public Health Service, attended a special ceremony in Ghana, in January 1968, to celebrate the 25 millionth vaccination given. George Lythcott (b. 1910), with sunglasses, was Director of the CDC regional office in Lagos from 1967 to 1972. An able and diplomatic administrator, Lythcott played an important role in sustaining the momentum of the programme through many political and logistic crises.

The pace of the vaccination campaign gradually accelerated. By January 1968, a special ceremony in Ghana marked the 25 millionth vaccination and by the summer of 1968 (Fig. 17.3), the numbers vaccinated had reached the optimistic estimates of January 1965.

The concurrent assessment of coverage, although deemed essential, was conducted in only 9 of the countries. The principal objection to assessment was that it wasted resources. Where it was performed, teams of 2 or 3 persons visited a random sample of 5–10% of the villages whose inhabitants had been vaccinated 4–10 days previously to ensure that the proportion of successful vaccinations was satisfactory and that coverage was adequate. Where coverage was found to be low, a repeat vaccination campaign was organized. Assessment data showed that good coverage was achieved in most countries (Table 17.5).

To ascertain the overall efficacy of the vaccination campaign, special surveys were conducted in 1968 in 5 areas—Dahomey, Niger, northern Nigeria, western Nigeria, and Togo—under the direction of Dr Ralph Henderson, then deputy director of the Lagos regional office (Henderson et al., 1973). With Mr Donald Eddins and Dr William Foege, he devised for the purpose of this survey a practical method of cluster sampling based on principles elaborated by CDC statisticians for immunization surveys in the USA (Serfling & Sherman, 1965). (The method was later adapted for use in WHO's Expanded Programme on Immunization, in nutrition surveys and in other health status assessments.) The survey revealed a generally satisfactory performance in most programmes. Nearly 80% of the people questioned reported having been vaccinated with jet injectors (Table 17.6). The low rates among those under 1 year of age

Nigeria, northern	88	84	25.6
Nigeria, western	60	76	9.3
Togo	80	88	3.1

could largely be accounted for by children born after the mass campaign; lower rates among those over 45 years were attributable to the fact that a number of older people had declined to be vaccinated, believing (correctly, in most instances) that they were already immune owing to previous disease or repeated vaccinations. The best results were obtained in northern Nigeria, in which cooperative, authoritarian emirs and district chiefs directed their subjects to accept vaccination; the lowest rates were found in western Nigeria, which lacked the tradition of authoritarian leadership and in which no concurrent assessment had been conducted.

Special comment is called for regarding the results obtained among children aged 0-4 years in Niger and northern Nigeria. In these areas, the proportion with a vaccination scar acquired at any time was lower than the proportion reported to have been vaccinated with the jet injector. This paradox can be partly explained by the possibility that some of the vaccinations by jet injector might have been unsuccessful or that parents might have reported that vaccinations had been performed when they had not. Because the surveys were conducted many months after the campaign, it proved impossible to determine the cause or to remedy the situation.

Of particular interest was the much higher proportion of persons in northern Nigeria with facial pockmarks, confirming a growing suspicion that this was the principal endemic focus of smallpox in western and central Africa.

### Coordination With International Organizations

Throughout the course of the programme, beginning with the initial planning visits, efforts were made by CDC staff to develop a collaborative working relationship with WHO through its Regional Office for Africa, the WHO representatives in the respective countries and two WHO smallpox advisers based in western Africa—one in Mali and the other in Liberia. These attempts were less successful than had been hoped, partly because the WHO regional adviser in Brazzaville who had been assigned responsibility for smallpox eradication had many other duties and could devote little time to the programme. Dr Mayer, the WHO adviser in

### Measles Control

Many valuable observations were made during the course of the programme with respect to the epidemiology and control of measles (Foster & Pifer, 1971), a disease which presented quite different problems from those of smallpox. Case-fatality rates associated with measles were customarily 4–5%, sufficient to identify it as second only to malaria as a cause of death among children. In contrast to smallpox, measles spread rapidly and widely. Studies in urban and in the more populous rural areas revealed that 50% of cases occurred in children less than 15 months of age (Smith & Foster, 1970a). Only in remote villages, where visitors were infrequent, did substantially higher proportions of cases occur among older children (Millar, 1970). In densely populated urban areas, morbidity decreased by about half for only 1 year following a mass vaccination campaign; in more sparsely populated areas, this decrease persisted for 2 years but the incidence then returned to pre-vaccination campaign levels (Smith & Foster, 1970b). In the hot and humid densely populated coastal areas, there was no apparent seasonal change in the frequency of transmission.

The prevention of measles infection was, and continues to be, a difficult problem. Essentially all children are born with circulating maternal antibody, which prevents infection. In some the protection is lost within 5 months, but in others it persists for up to 12 months of age. However, immunization is successful only after maternal antibody is lost, this antibody serving to protect against the attenuated infection induced by the measles virus vaccine. To prevent infection, therefore, it is necessary to administer the vaccine during the brief period between the time the child has lost the protection conferred by maternal antibody and his exposure to infection—in Africa, usually between 6 and 18 months. In a mass campaign in which vaccinations are given, for example, every 2–3 years to preschool children, much of the vaccine has no effect, these children being protected by maternal antibody or having already had the disease. Thus, the effect of a mass campaign on measles incidence is a transitory one. Efforts were made to vaccinate at more frequent intervals in urban areas of western Africa, but usually this had little effect unless the campaigns were conducted every 6 months, a prohibitively expensive strategy. Vaccination at conveniently located health centres was an alternative but in most areas there were few of these and most were not equipped with refrigerators. Thus, although the number of measles cases and deaths could be reduced, sometimes substantially for short periods of time, long-term control was not achieved.

Liberia, was WHO's intercountry adviser for all smallpox programmes in western and central Africa, but he could rarely travel. In 1968, he was transferred to Mauritania, where he served as the smallpox eradication programme adviser, the CDC adviser having had to leave Mauritania when diplomatic relations between that country and the USA were severed. The WHO adviser assigned to Mali rarely left the capital and in 1968 his post was discontinued. In response to requests from Member governments, the WHO Regional Office for Africa provided funds to cover local costs, 13 countries receiving in all a total of US\$1 110 675 over the period 1967–1972. However, apart from processing these requests, the regional office and the WHO

country representatives had little contact with the CDC programme.

From Geneva, Henderson maintained close contact with the CDC staff in Atlanta. They and selected national counterparts contributed to WHO interregional and intercountry smallpox seminars in Africa, South America and Asia; some WHO staff from the regions participated in the CDC smallpox eradication training programme in Atlanta in 1967 and 1968; and accounts of the progress made in western and central Africa were regularly published in the WHO *Weekly epidemiological record* and in special reports of the smallpox eradication programme. From 1968, supplies of bifurcated needles began to be shipped from Geneva, and in 1969 a jointly sponsored

WHO/AID/CDC conference on smallpox eradication was organized in Lagos. The extensive proceedings, which documented many important observations on smallpox eradication (United States National Communicable Disease Center, 1970), were distributed to WHO and national staff throughout the world.

Collaboration with OCCGE and OCEAC was effective and useful. These organizations, both supported by France, kept abreast of events through written reports and discussions at their semi-annual meetings, which dealt with the progress and policies of this and other regional programmes. The directors of these organizations also participated actively in solving problems of implementation and communication arising in programmes conducted by their member governments. In addition, OCEAC served as an intermediary for the transmittal of national reports and the receipt of supplies and equipment for the Congo, with which the USA did not then have formal diplomatic relations; beginning in 1968, OCCGE performed a similar function with respect to Mauritania.

### **Changing Roles of the CDC Atlanta Office and the Lagos Regional Office**

Flexibility in the management structure was no less important than in field operations. The Lagos regional office had been expected to serve as the principal point of contact for operations and as the conduit for reports and requests from all the national programmes; the CDC Atlanta office was expected to bear primary responsibility for recruitment, training, procurement of supplies and equipment and liaison with AID. This management relationship had originally appeared to be the most logical because of the geographical proximity of the Lagos office staff to field operations and of the less elaborate procedures that would be needed to obtain United States government approval for travel by persons stationed abroad. What had seemed logical during the planning stage, however, proved less functional in practice. It soon became apparent that communication between the individual countries and Atlanta was usually easier than between them and Lagos. When a protracted civil war broke out in Nigeria in 1967, the difficulties became greater as cable traffic increased. Because messages concerned with the smallpox eradi-

cation-measles control programme were given low priority, a cable from a national capital sent through Lagos took as long as 1-2 weeks to reach Atlanta. Shipments of supplies by air freight or diplomatic pouch were also delivered more promptly when dispatched from Atlanta than from Lagos. Although it was a major transport centre, Lagos had few direct flights to many of the African capitals, especially those of the francophone countries. In consequence, field staff and personnel in Atlanta, faced with an increasing array of problems, found it necessary to communicate direct with each other.

Towards the end of the first year, responsibilities and relationships were redefined to centralize direction in Atlanta, the Lagos office assuming a support role in contacts with national authorities and undertaking special investigations and assessments. In practice, the revised system worked well: new approaches were identified as experience accrued, and alternative methods and systems found useful in one country were applied with little delay throughout the region.

### **Surveillance and Containment Activities**

It had been thought at first that surveillance and containment activities would be most crucial to interrupting transmission during the concluding phases of each of the national mass campaigns, but experience quickly showed that they could play a vital role from the beginning of a programme, irrespective of smallpox incidence. This was first shown in eastern Nigeria, just as the regional programme began.

The Nigerian programme agreement was signed on 6 October 1966 and field staff soon began to arrive. Operations were, however, initially confined to 2 of Nigeria's 4 regions because special agreements had to be finalized with each of the semi-autonomous regions before work could begin. The Eastern Region was the first to commence operations. In November 1966, Dr Foege with Dr David Thompson and Mr Paul Litchfield, began a programme of staff training while awaiting delivery of vehicles and other commodities. Early in December, they were informed by a missionary of smallpox cases in a small village and decided to use this opportunity to train vaccination teams in containment activities. Using borrowed transport, they vaccinated people in the

village and along nearby roads; an outbreak of 19 cases was stopped in 4 weeks (Foege et al., 1975). Missionaries in the southern part of the Eastern Region, who had their own radio network, were approached for help in notifying other outbreaks. Two further outbreaks were soon identified, one of 14 cases and one of 5 cases. Both were contained within 3 weeks, again simply by vaccinating household and village contacts. With the limited resources available, the programme staff had expected to do little more than control a few of an anticipated large number of outbreaks, but surprisingly no further outbreaks were reported in this area. On investigation, the staff discovered that the last epidemic to be recorded in the area had occurred in 1950, despite the fact that comparatively few persons, except those living near roads, had been vaccinated since then. The first case in the 1966 outbreaks had come from the Northern Region of Nigeria fully 5 months before; subsequently, smallpox had spread slowly southwards with as many as 4 generations of cases occurring in a single compound. The finding of so few outbreaks, all in nearby villages, along with the discovery that they could be rapidly contained even where vaccinal immunity was low, was impressive. A review of data from earlier years suggested that outbreaks normally began along the northern borders of the region and spread progressively towards the south, an observation which suggested that persistent endemic transmission did not occur in most of the Eastern Region.

The programme staff decided to concentrate their resources in areas in which smallpox was known to be present. Accordingly, a new reporting system was devised. In each of the 3 provinces of the Eastern Region, a reporting officer was designated to obtain weekly reports from all government and missionary health establishments and transmit them by radio directly to Enugu, the regional capital. The data quickly revealed that most of the known cases were occurring along the northern boundaries, and a pilot vaccination campaign was therefore begun in the northern urban area of Abakiliki (WHO/SE/68.3, Thompson & Foege). Within a week, 46 500 people were vaccinated and gradually the campaign moved to adjacent areas in the savanna. Numerous unreported cases of smallpox were discovered and, by May 1967, 754 cases with 180 deaths had been documented.

Meanwhile, political turmoil steadily increased throughout the Eastern Region and on 30 May the predominantly Ibo tribal population seceded from Nigeria, proclaiming the independent Republic of Biafra. It became increasingly difficult to continue with the programme; travel was restricted to those with special passes, and petrol became scarce. Nevertheless, during June 1967, a mass vaccination campaign was conducted in and around Enugu—the only remaining endemic focus. By the end of the month, transmission appeared to have ended, after only 6 months of activity, during which only 750 000 of the 12 million inhabitants had been vaccinated (Foege et al., 1971). Programme operations in eastern Nigeria were interrupted almost immediately thereafter but the idea had been planted that it might be desirable to give precedence to the discovery and containment of outbreaks over the execution of the mass vaccination campaign.

By June 1968, vaccination teams were active in 19 countries; some 40 million persons had been vaccinated—about 35% of the estimated population. In each programme, priority was given to vaccination campaigns in the areas reporting the most cases of smallpox, although this strategy was not pursued with the same vigour as in eastern Nigeria. Less than half the countries had independent assessment teams but in most of them documentary or other evidence indicated that the vaccination coverage was high. The impact of the vaccination campaign was already apparent, only 2312 cases being reported by the end of May compared with 4071 during the same period of the preceding year. Although reporting systems were still inadequate, many cases which would not otherwise have been reported were being detected by vaccination teams, and some during outbreak investigations, where these were being undertaken.

In June 1968, Dr Foege, who had joined CDC's Atlanta staff, proposed to participants at the annual CDC Regional Programme Conference a change in strategy to hasten eradication—namely, to give priority to the detection and containment of outbreaks (Foege et al., 1971). Originally, there had been doubt that simple containment measures could be effective because of the common belief that smallpox was comparatively easily and rapidly transmitted through the population (Felsenfeld, 1966; Top, 1968), especially where vaccinal immunity was low. The

experience in eastern Nigeria and a study in Dahomey in 1967 (Henderson & Yekpe, 1969) contradicted this. Moreover, epidemiological studies of smallpox in East and West Pakistan in 1966-1967 (Thomas et al., 1971a,b, 1972; Mack et al., 1972a,b) also showed that smallpox spread slowly, that outbreaks tended to be clustered in an area rather than widely dispersed and that at the low point of seasonal incidence very few villages were infected. These observations were also confirmed in India in a study conducted in a district classified as heavily infected but in which it was found that at no time were more than 1% of all its villages infected with smallpox (India National Institute of Communicable Diseases, 1968).

Dr Foege reasoned, as had the investigators in Pakistan, that intensive efforts to detect and contain outbreaks, if begun at the low point of seasonal incidence (September-October), should readily contain the few outbreaks then present. This would serve to avert major epidemics later in the year, when smallpox spread more rapidly. He proposed that each of 8 countries which then had endemic smallpox should undertake an intensive and continuing programme of surveillance and containment. The programme was given the name E<sup>2</sup>, for "eradication-escalation" (Foege et al., 1971). The strategy was formally adopted in July 1968 by all countries except Nigeria, which decided that because of a widening civil war, it would give priority to completion of its mass vaccination campaign. However, in areas of Nigeria in which mass vaccination had been conducted, specially assigned short-term CDC epidemiologists would undertake outbreak investigation and containment.

For the detection of cases, the usual reporting mechanism was augmented by the cooperative efforts of other special health service programmes (e.g., leprosy and malaria control), government personnel, village leaders and non-governmental bodies such as missions. Outbreaks were investigated and vaccination was performed in a "geographically or socially contiguous area around each patient", as determined by epidemiological investigation. The area was not defined more explicitly, as was later done in Asia, nor was an attempt made to enumerate contacts and village populations to ensure that all had been vaccinated.

The increase in surveillance activity led to the discovery of many additional cases, with the result that the number of reported cases rose from 197 in August to 289 in September; from then on, it fell steadily (Table 17.7).

By January 1969, endemic smallpox remained only in Dahomey, Nigeria, Sierra Leone and Togo. The last cases in Sierra Leone and Togo were detected in May of that year, and the last case in Dahomey was found in September; thereafter no further cases were notified for 6 months (Table 17.8). In March 1970, however, a persistent endemic focus was discovered in northern Nigeria, but 2 months later the last known case in Nigeria, the last in western and central Africa, was detected, only 9 months after "eradication-escalation" had begun.

The vaccination campaign continued throughout the "eradication-escalation" operation, 33 million persons being vaccinated during 1969 and 22 million in 1970 (Table 17.9). Contrary to expectations, the pace of the vaccination campaign did not diminish during this period; indeed, more vaccinations

<sup>a</sup> No other countries in western and central Africa reported cases after 1968.<sup>b</sup> Figures in parentheses denote cases recorded by date of onset rather than by date of notification; these cases were discovered on 21 March and during succeeding weeks.<sup>c</sup> Reported to be importations from the Northern Region of Nigeria.<sup>d</sup> Cases reported in January 1969; the onset of the last case was in December 1968.<sup>e</sup> Cases reported in May 1969; the onset of the last case was in April 1969.

were given each week, on average, than before the special programme began. By the end of 1970, the number of vaccinations performed in 12 of the countries was equivalent to, or greater than, the estimated population.

During 1971-1972, the programme was modified in order to give priority to the vaccination of those who had been missed during the initial mass campaign and of those born after it. By the end of 1972, 153 484 000 smallpox vaccinations and 28 163 000 measles vaccinations had been performed. The cost of smallpox eradication in the region was estimated to be US\$0.138 per head of population (Foege et al., 1975).

In 1972, as the 5-year programme drew to a close, CDC staff proposed to AID that other types of vaccine and support for other preventive measures should be provided in order to strengthen the health services in the countries of western and central Africa. Although the proposal was endorsed by all the ambassadors of the USA in the region, as well as the respective health ministers, the programme was terminated at the end of 1972. CDC sought to sustain surveillance and a maintenance vaccination programme by assigning epidemiologists to OCCGE and OCEAC, but because of the large number of countries and the lack of supplies and equipment to replenish the programmes, vaccinal immunity steadily declined thereafter as did the quality of surveillance. By 1976, when precertification activities had to be undertaken, special programmes had to be initiated in all the countries of the region to document what had been accomplished and to verify, through pockmark surveys, that no further cases had occurred.

## NATIONAL PROGRAMMES

Each of the national programmes had different characteristics and encountered different types of problems, some of which are summarized and discussed below. For ease of presentation, the countries are dealt with in 7 groups (shown in Fig. 17.1): (1) Nigeria—the most populous country, which, between 1967 and 1970, reported 6854 (40%) of the region's 17 106 cases; (2) Dahomey and Togo—2 small adjacent coastal countries, in which smallpox incidence was high, and in which there was resistance to vaccination because of fetish practices; (3) Mali, Niger and Upper Volta—3 inland Sahelian countries, in which

### Guinea-Bissau

Throughout the duration of the AID-supported smallpox eradication programme in western and central Africa, the status of smallpox in Guinea-Bissau was uncertain and caused concern. Until 1974, when Guinea-Bissau became independent, the Portuguese colonial administration reported regularly that no smallpox cases had occurred. However, there was widespread civil war, with rebel forces reputed to be in control of two-thirds of the country. The adjacent country of Senegal remained smallpox-free and posed no threat, but extensive epidemics occurred in many parts of Guinea, in which the bases of the rebel forces were located. Officially, nothing could be done to support activities in Guinea-Bissau but, as was the case in the Sudan, which also experienced protracted civil war (see Chapter 18), leaders of the rebel forces evinced concern about smallpox. They sent health workers for training in Guinea, which provided vaccine and bifurcated needles. Health staff in the rebel-held areas also reported periodically on smallpox. So far as could be ascertained at the time, and later during certification surveys, no cases of smallpox occurred in Guinea-Bissau during this period.

there were many nomads and frequent transhumance; (4) Guinea and Sierra Leone—2 highly endemic countries, in which programmes were launched nearly a year later

than in the other groups but which succeeded in interrupting transmission within 18 months; (5) Côte d'Ivoire, Ghana and Liberia—3 adjoining countries on the southern coast of western Africa, which experienced few cases of smallpox after 1966; (6) the Gambia, Mauritania and Senegal—all of which were free of smallpox when the programme began, and remained so; and (7) the OCEAC countries—only 2 of which (Cameroon and Chad) detected cases of smallpox after 1966, mostly imported from Nigeria. Guinea-Bissau's status is summarized in the accompanying box; activities in Equatorial Guinea, which remained free of smallpox and in which no special programme was conducted, are not further described.

### Nigeria

Nigeria (population in 1967, 51.9 million) was the crucial country for the smallpox eradication programme, being centrally located and heavily endemic (Fig. 17.4) and having a population totalling nearly half that of the entire region. The largest number of CDC technical staff were therefore assigned to Nigeria and the CDC regional programme office was located there.

When the programme began, Nigeria was a federal republic consisting of 4 regions and the federal district of Lagos. Because responsibility for health matters was delegated to the

regions, programme policies and plans had to be worked out and agreed on not only at the federal level but with each regional authority as well. Each region, in turn, dealt with traditional tribal authorities, which, in the Northern Region, had substantial powers. The National Council on Health had decided in 1962 that the eradication of smallpox should be an objective of national policy (Foster & Smith, 1970) and plans for such a programme were developed by the Principal Medical Officer of the Ministry of Health of Nigeria, Dr G. A. Ademola. Implementation of the programme, however, had to be delayed until 1967, when resources were made available by AID. Meanwhile, thermolabile lantolinated vaccine, produced in a government laboratory in Lagos, was provided for use in health centres, but because it was rarely kept under refrigeration, many of the vaccinations were unsuccessful. Mobile field teams, which periodically undertook mass vaccination campaigns, undoubtedly improved vaccinal immunity in the Eastern, Western and Mid-Western Regions. However, nowhere was the level of immunity high, and in the Northern Region, vaccination coverage was especially poor.

Pockmark surveys conducted after the AID-supported programme began revealed that smallpox had been widely prevalent throughout Nigeria during the early 1960s, an estimated 100 000 or more cases having occurred annually. Survey data, as well as morbidity data compiled in 1967 (Fig. 17.5), showed the Northern Region to be the most heavily afflicted. In this region, which consisted mainly of savanna and arid scrub, the highest incidence occurred in the dry season, from January to May; in coastal areas, seasonal changes were less marked. The case-fatality rate was probably about 10%, although the only available data pertain to persons admitted to hospital—usually those who were the sickest and among whom deaths would have been more frequent (Table 17.10).

Early in 1967, Nigeria was on the brink of civil war. As major tribal groups vied for power, a military government displaced civilian rule, and an army mutiny occurred in the north, accompanied by extensive riots. The Eastern Region of the country threatened to secede. Despite these serious problems, the government supported the smallpox eradication programme. Pilot activities, each with its own programme unit, began in Lagos and in the Eastern and Western Regions during the

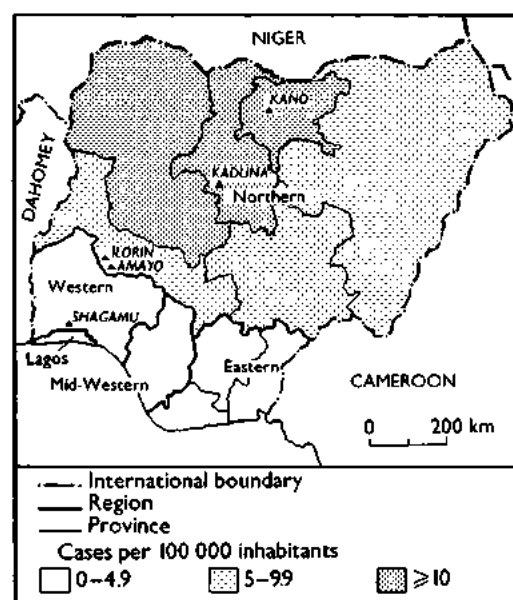

Fig. 17.5. Nigeria: smallpox incidence by administrative region and province, 1967. Early in 1967, Nigeria was made up of 4 regions and the federal capital territory of Lagos. The map also shows the provincial subdivisions in the Northern and Eastern Regions.

spring of 1967 and in the Northern and Mid-Western Regions during the summer. Because of the widespread prevalence of smallpox and concern as to the continuing stability of the country, Dr Ademola and Dr Stanley Foster, the CDC senior adviser, decided to devote all available resources to the mass vaccination campaign, giving first priority to the areas with the highest incidence in each region.

Table 17.10. Nigeria: number of cases of and deaths from smallpox, and case-fatality rate, in Kano Infectious Diseases Hospital, by age, 1967-1970

Total	1 090	129	12

The responsibility for outbreak control was left to local health authorities, to which the government continued to issue lanolinated vaccine despite advice to the contrary by CDC staff.

In the Eastern Region, smallpox was eliminated with surprising rapidity. Mass vaccination in the north of that region, in which cases were concentrated, concluded in June 1967, simultaneously with the occurrence of the last known smallpox cases. In July, the Eastern Region having declared itself the independent Republic of Biafra, fighting between the Nigerian and Biafran armies began along its borders. The vaccination campaign decreased in intensity but did not stop immediately, and for many months vaccine continued to be transferred from Nigerian to Biafran health authorities during cease-fire periods arranged for this purpose. By the end of 1967, however, vaccination had ceased, and in 1968 widespread famine developed in Biafra, accompanied by epidemics

of measles with high case-fatality rates. In October, the government of Biafra appealed for help and the International Committee of the Red Cross (ICRC) and the World Council of Churches responded with technical assistance and provided measles and smallpox vaccines, the latter coming from WHO stocks in Geneva. A vaccination campaign began again on 27 December 1968, organized by Dr A. E. Ifekwunigwe, a senior lecturer in paediatrics at the university in Enugu, Dr Nicole Grasset of the Institut Pasteur (Paris) and Dr A. T. C. Bourke, consultant to the ICRC. Despite serious shortages of petrol and staggering problems of transport and communication, 11 teams succeeded during the following year in giving an average of 100 000 smallpox vaccinations and 3500 measles vaccinations each week. Suspected cases of smallpox were investigated and specimens sent to Geneva for examination by WHO reference laboratories, but none contained smallpox virus.

**Plate 17.10.** The secession of the Eastern Region of Nigeria and the civil war that ensued resulted in extensive famine throughout that area. Despite formidable problems and great personal danger, national and international staff undertook extensive smallpox and measles vaccination campaigns, with special attention to refugees in camps.

Meanwhile, by the beginning of May 1967, a pilot project in Lagos had been completed during which 1 million persons were vaccinated against smallpox; in February, the Western Region began its programme and in July more than 750 000 were vaccinated in Ibadan, the capital. Assessment showed that 90.8% of the population had been vaccinated. In the Northern Region, however, problems in reaching agreement about the conduct of the programme delayed its start until July. The vaccination campaign began in the western part of the region, in which the reported smallpox incidence was highest, and moved progressively eastwards, achieving substantially higher levels of coverage than in other parts of the country. The better coverage was achieved as a result of the edict of tribal leaders that people accept vaccination or be fined if they refused. As one programme officer commented: "In the south, a health education programme had to reach all the people to convince them to participate in a health activity, whereas in the north, a health educator only had to convince the emirs."

By the end of 1967, some 9.5 million smallpox vaccinations had been performed in Nigeria. A monthly mimeographed "Nigerian Smallpox Eradication-Measles Control Surveillance Report," which first appeared in April of that year, informed health staff throughout the country about the efforts being made. The number of cases reported in 1967 (4753) differed little from the 1966 figure (4953), most of the cases being reported during the first half of the year, primarily from the Northern Region.

Although the national programme had proceeded at a slower pace than planned, it was remarkable that so much progress had been made in a country engaged in full-scale civil war. There were problems in the delivery of supplies by air and sea, serious impediments to travel, shortages of petrol and other supplies and considerable personal risk to the teams working near the areas bordering on Biafra. Imagination, persistence and courage were required of national staff and CDC advisers alike: Dr Ademola and Dr Emmanuel A. Smith, the national programme director; Dr J. I. Adetosoye, Dr I. S. Mebitaghan and Dr P. O. Adeoye, Nigerian directors of programmes in the west, mid-west and north, respectively; and their CDC counterparts, Dr Margaret Grigsby (succeeded by Mr Lloyd Wade), Mr Warren Jones (succeeded by Mr Paul Bond) and Dr Deane Hutchins (succeeded

ed by Mr Robert Hogan). The age distribution of cases of smallpox for which ages were recorded closely resembled that of the general population (Table 17.11), suggesting that where outbreaks occurred, primarily in rural areas, immunity was low throughout the population.

Problems in northern Nigeria continued to be substantially greater than in other regions, partly because of its size, the lack of roads and the relative paucity of health facilities, and partly because many of the senior administrative and technical staff, including mechanics, had been Ibos from the Eastern Region who had fled with the onset of war. Only 3 CDC technical staff had originally been assigned to assist, but in April 1968 their number was increased to 6 and the CDC regional office equipment specialist was transferred to Kaduna to train new mechanics in the repair and maintenance of some 60 vehicles and jet injectors. Operations were further complicated, however, by the government's decision to divide the region into 6 states, a move which required many modifications in the programme, including the reassignment of supervisors and field personnel, the restructuring of the reporting system, and changes in the budget and payment systems.

As 1968 advanced, the programme in Nigeria became fully established and during the year almost 24 million persons were vaccinated against smallpox by 60 mobile teams. In the Northern Region, assessment teams, visiting areas 7-14 days after the population had been vaccinated, usually found coverage levels of 95% or higher. For assessment elsewhere, the authorities decided to use the less satisfactory method of comparing the number of vaccinations performed with the population census figure. Although the personnel of the Western Region pro-

### Vaccine Production in Nigeria

From 1967 onwards, both CDC and WHO provided support to a government vaccine production laboratory at Yaba, near Lagos, in the hope that it might be able to manufacture sufficient high-quality freeze-dried vaccine to meet the needs of Nigeria and perhaps of other countries in western Africa. A CDC virologist, Mr Nathaniel Rothstein, was appointed to the laboratory in 1967 and, later, a WHO expert in vaccine production, Mr Ronald C. Kent, was assigned there and remained until 1976. Nigerian laboratory staff, assisted by WHO fellowships, received training in the United Kingdom, and the necessary laboratory equipment was provided by WHO. Batches of freeze-dried vaccine began to be produced in 1968 but the vaccine did not meet international standards until 1974, and then only briefly. Frequent transfers of technical personnel and management problems hampered work throughout this period. Nevertheless, the vaccine was routinely distributed for use in health centres, the vaccination teams using vaccine supplied by the USA. After 1973, the laboratory supplied all the vaccine required in Nigeria.

gramme regularly estimated the coverage to be 90% or greater, later surveys showed levels of 80% in towns of more than 5000 inhabitants and levels as low as 45-65% in the villages.

In September 1968, with the introduction of the regional "eradication-escalation" programme, efforts were made in Nigeria to improve the reporting system, which was complex and functioning poorly, some reports being delayed for weeks or even months—if they were sent at all. The system required the responsible village heads to report suspected cases to a district superintendent, and although some complied, many did not. The district superintendent, in turn, was expected to inform the superintendent for health, who was supposed to institute control measures and to forward his report to an area medical officer, who in turn reported to the regional government. Such outbreak control measures as were undertaken were largely ineffective, since the lanolinated vaccine continued to be distributed to the local health authorities. In the hope of improving reporting, efforts were made to persuade teachers, missionaries, foreign volunteers and others to report cases by recording the details on stamped addressed postcards, which had been duly supplied. In practice, however, this activity had little effect.

Although the epidemiological observations in eastern Nigeria had generated the "eradication-escalation" strategy, Nigerian staff and their CDC counterparts decided not

to divert resources to this undertaking. As they assessed the situation, surveillance in northern Nigeria, in which virtually all cases were then occurring, could be established only with difficulty and over time because health centres were few, experienced personnel were lacking and the population was widely dispersed. In view of the continuing war, it was uncertain whether vaccination teams would have access to many areas in the future. Because the mass vaccination campaign was progressing well, with high levels of coverage, it seemed to the personnel concerned that the most prudent course would be to complete the campaign as rapidly as possible. That being accomplished, resources could be diverted to the investigation and containment of outbreaks. Limited surveillance activities were begun, however, towards the end of 1968, using short-term CDC epidemiologists in areas in which mass vaccination had been completed. At that time cases were found to be occurring in small outbreaks primarily among semi-nomadic Fulani herders. Having no special allegiance to the principal tribal leaders, these groups had largely been missed by the vaccination teams and by assessment teams as well (WHO/SE/68.5, Pifer & Adeoye).

The mass vaccination campaign continued to progress rapidly, concluding in the autumn of 1969. Meanwhile, the number of reported cases of smallpox declined sharply, only 5-16 cases being recorded each month from March to the end of July 1969. After July, no further

### Northern Nigeria: the Role of Traditional Leaders

In northern Nigeria, strong traditional tribal leadership both helped and hindered programme implementation. One adviser recalled his surprise when attending the first mass vaccination campaign in a town to find 6000 persons already in a line at 6 o'clock in the morning. As the day progressed, he proposed to the chief that a vaccination team should move to the market area to begin work there. The chief forbade this, indicating that if all vaccinations were performed in front of him, everyone would comply, but if he were not present at the vaccination assembly point, people would report they had been vaccinated when they had not. Vaccination in this and other largely Muslim northern cities continued until long after dark, as women were not allowed to leave their homes until nightfall.

On the negative side were such problems as those encountered during the investigation of the outbreaks in 1970 in and around Amayo. A village chief, when questioned about rumours of smallpox cases, denied all knowledge of them until, during the course of interrogation, his granddaughter emerged from the house with evident smallpox lesions. Because of fear that he would be deposed from his chieftaincy if it were found that he had been hiding cases, he had suppressed information about the outbreaks.

cases were detected that year although an average of 10 rumours were investigated each month (WHO/SE/71.30, Foege). Transmission appeared to have been interrupted and, with the last cases occurring in Dahomey in September 1969, national and CDC staff scheduled a celebration for the end of March 1970 to mark the eradication of smallpox from western and central Africa. On 21 March, just as the staff were preparing to depart for the celebration, a 14-year-old girl was admitted to the infectious diseases hospital in Kaduna (Fig. 17.6) with unmistakable smallpox (*Wkly epidem. rec.*, 1970b). She had fallen ill shortly after arriving from the town of Amayo (population, 1400), Kwara State, some 400 kilometres away. The outbreak was discovered almost simultaneously by a state senior health superintendent. Intensive house-to-house vaccination and search for cases revealed 48 additional cases in the town (WHO/SE/71.30, Foege) and 12 other cases in neighbouring villages, the first cases in the outbreak having occurred in October 1969. Further investigation revealed that smallpox transmission had persisted in the area since early 1969, primarily in communities of up to 300 persons, the cases being hidden by their families from the health authorities. The search was extended to Ilorin, the capital of Kwara State (population, 300 000), only 11 kilometres away. Nine additional cases were found—the last on 22 April 1970.

Vaccination in Kwara State had been conducted between December 1968 and July 1969. However, the reassignment of personnel, which accompanied the division of the Northern Region into states, had left Kwara with fewer resources than other states, and the supervision of the programme had been poor. Teams had concentrated their efforts in the major villages and towns, but even there coverage was poor because villagers resisted vaccination. During assessment, it had been

Fig. 17.6. Nigeria: number of reported cases of smallpox, by week of onset and by area, October 1969–May 1970.

found that coverage was only 70% in rural areas and 60% in the town of Ilorin; a repeat campaign had therefore been conducted in the course of which 97 000 additional vaccinations had been performed. Despite this effort, a survey in April 1970 showed that only 77% of the population had vaccination scars; in some peripheral areas of the city, the proportion was only 35%. Following the discovery of the outbreak in April 1970, a repeat house-to-house vaccination campaign was conducted, and road-blocks were established around the city to vaccinate any person who entered or left. Subsequently, special teams conducted village-by-village searches and vaccinated the inhabitants of the surrounding districts; special district search teams continued work during the following 12 months. The last known case in the area, however, occurred during the second week of April, 3 weeks after containment operations had begun.

Just as the outbreaks in the Amayo Ilorin area began to come under control, a more alarming discovery was made: 2 cases had occurred in Lagos, 150 kilometres to the south, the patients having become ill during April. Three further cases, with onset of illness in May, were discovered in Shagamu, a town to the north of Lagos. The source of infection in both outbreaks was suspected to be Ilorin, but this could not be confirmed. Intensive search and vaccination were extended in ever-widening areas around these 2 foci but no further cases were found.

The occurrence of new, widely scattered outbreaks in Nigeria was profoundly disturbing to staff throughout western and central Africa, since the cases were discovered more than 6 months after it had been thought that transmission had been interrupted and more than a year after the intensified surveillance scheme had been launched. Optimism and complacency were quickly replaced by doubt and a redoubled surveillance effort. No celebrations were in fact held until more than a year later. Although the cases in Shagamu proved to be the last, the intensified search that their presence had stimulated gave grounds for confidence that transmission had indeed been interrupted.

### Dahomey and Togo

In 1967, Dahomey (population, 2.5 million) and Togo (population, 1.8 million),

former colonies of France lying on the Bight of Benin between Nigeria and Ghana, were impoverished and politically unstable. Together, they cover an area between 250 and 500 kilometres from east to west and 650 kilometres from north to south. In both countries, the population was concentrated in the south. Travel from one to the other and to neighbouring countries was unrestricted and frequent because the presence of tribal groups extended across national borders. In contrast to most of the former French colonies in Africa, traditional tribal leadership remained strong and the civil governments were comparatively weak and unstable. Togo experienced 2 *coups d'état* in the 4 years immediately preceding the smallpox eradication-measles control programme; and Dahomey 6 *coups d'état* between 1960 and 1970, its first decade of independence.

Preventive medical services in both countries had all but ceased to function by 1967 because of political upheaval and lack of funds. Dahomey had had a reasonably effective mobile endemic diseases control service, which had functioned like its counterparts in other former French colonies. As recently as 1965, it had had a complement of 237 staff, operating from headquarters posts in the southern, central and northern parts of the country. The number of vaccinations given each year had been equivalent to 20–25% of the population. The activities of the service had, however, gradually diminished, and by 1967 little field work was being done. Togo had also had a mobile endemic diseases control service, which was less well supported and had effectively been disbanded in 1964–1965. The number of vaccinations performed and the type of vaccine used are not recorded.

In both countries, substantial numbers of smallpox cases were reported every year (Table 17.12), primarily from southern areas. There, as in parts of western Nigeria, resistance to vaccination had been widespread, especially in the more rural areas. The resistance was attributed to the cult worship of a smallpox fetish (see Plate 17.11) called Vodou-Sakpate, or Sozona, the major earth god of the Fon tribe. Hereditary fetish priests (*féticheurs*), who were thought by the people to have the power to prevent or to induce the disease, had traditionally performed variolation by the inoculation of pulverized scabs on the forehead, at the base of the nose or on the underside of the wrist (Gloekpor, 1970). Customarily, large numbers of persons were

variolated in an affected village some 3–4 weeks after the onset of illness in the first case, in a ceremony which was said to “free the patient” of illness. For the *féticheurs*, there were economic disincentives to cooperate in vaccination campaigns, since they were customarily given all the possessions of a patient who died of smallpox. Concern about the problem was reinforced by information that a vaccination team in Dahomey had been killed by fetish worshippers in the early 1960s.

Table 17.12. Dahomey and Togo: number of reported cases of smallpox, 1962–1969

Year	Number of cases	
	Dahomey	Togo
1962	132	571
1963	249	285
1964	703	34
1965	168	13
1966	490	201
1967	815	332
1968	367	784
1969	58	83

In Dahomey, personnel from the endemic diseases control service were again employed for a mass vaccination campaign, which commenced simultaneously in April 1967 in the northern, central and southern zones of the country. At the beginning, progress was discouragingly slow, since by government decision smallpox vaccine and measles vaccine were given by separate teams. Ultimately, however, the practice was changed and each team gave both kinds of vaccine, which resulted in a considerable improvement in programme efficiency and a reduction in cost. Better progress was also made when it was realized that tribal chiefs, especially in the southern areas, were more influential than the civil authorities. Accordingly, meetings began to be arranged with tribal authorities to explain the programme's goals and method of operation and to discourage variolation.

In August 1967, soon after the programme had begun, a special study of a small outbreak revealed quite a different epidemiological picture of smallpox in this area from that which had been anticipated (Henderson & Yekpe, 1969), a finding which contributed to

WHO/P. PI/TET

Plate 17.11. The practice of variolation and resistance to visits by vaccination teams were both associated with fetish worship. At a celebration in Dahomey, a priestess dances in front of the smallpox fetish until she goes into a trance.

the formulation of the 1968 "eradication-escalation" strategy. The investigation began 10 weeks after the occurrence of the first case, but only 28 cases were found in the village of 300 inhabitants, despite the fact that only 15% of the children and 54% of the total population had vaccination scars. Surprisingly, the outbreak had terminated spontaneously, notwithstanding the many remaining susceptible persons. The study, which was conducted by Dr Ralph Henderson and Dr Maximilien Yekpe, chief of the southern sector of the endemic diseases control service, showed, moreover, that the patients were geographically clustered within the village itself despite the frequent movement of the population throughout the village. These observations reinforced the belief that smallpox in Africa spread slowly and that transmission occurred primarily as a result of intimate personal contact in households and rarely through casual contact in market-places or elsewhere. Given this pattern of spread, outbreak control was clearly more feasible than had been expected.

Assessment of the vaccination programme in Dahomey during 1967 revealed that only 28% of the population were being vaccinated by the teams and that the more remote, less accessible villages and hamlets were being missed; in some of these, smallpox outbreaks occurred after the teams had left the area. To complement the work of mobile teams who vaccinated only at assembly points, a group of 12 young health workers, called "*les douze*," was recruited, trained and given motor cycles. They worked in areas in which coverage was poor, performing house-to-house searches and vaccinating, by means of bifurcated needles, all children under 5 years of age and anybody without a vaccination scar (Yekpe, 1970).

The programme in Togo likewise got off to a slow start in 1967. The vaccination teams consisted of staff from a yaws control programme, who had continued to receive their pay but had not worked for more than 2 years. They were unenthusiastic about performing the requisite field work and made a poor showing until threatened with suspension. For political reasons, the vaccination campaign began in the north but, after a *coup d'état* and a change of government, it shifted to the south, where most cases were being reported and where villagers were both resistant to vaccination and suspicious of the government teams. The problems encountered may be

illustrated by the description of an outbreak investigation conducted in November by the CDC advisers, Dr Bernard Challenor and Mr Andrew Agle. On checking a rumour of smallpox cases in a village whose inhabitants had been vaccinated twice, in January 1967 and again in October of that year, they found 8 patients, 7 of whom were hidden in the bush. The director of the medical zone, who was disturbed by these observations, decided to obtain help from the police and to take village chiefs into custody until the inhabitants of their villages had all been vaccinated. As in most areas in which police or military force was used, the result was even less satisfactory than before, since chiefs and villagers fled the area or fought with the police. That approach was soon abandoned.

Despite all the difficulties, 605 000 vaccinations were recorded in Togo in 1967 and 702 000 in Dahomey, which approximated to the projected targets. In that year the number of cases reached 815 in Dahomey and 332 in Togo, an incidence in each country which was among the highest in the world.

During the course of 1968, both countries significantly improved their reporting systems and gradually the proportion of people vaccinated in each area increased. Programme staff in both countries enlisted the help of personnel in health clinics, other health workers, foreign volunteers and tribal authorities to report cases. In south-eastern Togo, 15 health workers, comparable to "*les douze*" in Dahomey, were assigned to visit each house monthly in designated problem areas to vaccinate residents and to detect cases. In both countries, surveillance systems gradually improved and by late 1968 were well established, effective national programme leadership being provided by Dr G. F. Gloppe, Chief of the Division of Epidemiology in the Ministry of Health in Togo, and by Dr Yekpe in Dahomey. The number of vaccinations in 1968 rose to 990 000 in Dahomey but remained almost at the same level as in 1967 in Togo. In 1968, the number of reported cases decreased to 367 in Dahomey but rose to 784 in Togo—mainly owing to more complete notification.

The continuing high incidence of smallpox in Togo and reports that the entire population of villages had fled from the teams led to two studies in January 1969, one to determine what role fetish worship played in resistance to vaccination and what could be done about it, and the other to ascertain overall levels of

Table 17.13. Togo: levels of smallpox immunity by age, January 1969

Age group (years)	Persons examined				Percentage Immune

vaccinial immunity. Mr Gordon Robbins, the health education adviser from the CDC regional office in Lagos, conducted the fetishism study (Robbins, 1970). He discovered that the resistance to vaccination had less to do with fetish practices and attitudes than with the concern of villagers about government teams in general, many of which were then engaged in tax collection and military conscription. As he learned, many of the *feticheurs* themselves, as well as their families, had been vaccinated. To measure overall levels of immunity, a national cluster sample survey was conducted. The survey showed that

immunity was surprisingly high in all age groups, except among infants under 1 year of age (Table 17.13). From these findings, it seemed unlikely that smallpox transmission could persist for long, especially with the greatly strengthened systems for case detection and containment then operating. Indeed, the last case in Togo occurred in May and the last in Dahomey in September.

Observations made during the surveillance programme in Togo during 1969 are of interest (WHO/SE/70.21, Glokpor & Agle). In that year 45 outbreaks were reported, of which 17 were notified by the routine report-

ing centres, comprising 190 dispensaries and polyclinics and 15 hospitals; 9 were found by smallpox teams in the field; and 19 were reported by other sources. The other sources included a radio-club president, village chiefs, a civil administrator, a social worker, an employee of the social welfare bureau, and members of malaria control spraying teams. Twenty-five of the 45 reported outbreaks were confirmed to be smallpox; two-thirds of the outbreaks and more than half the cases were in generally remote and isolated villages of less than 200 inhabitants. In these places vaccination coverage was usually found to be lower than 50%.

The differences between the number of smallpox cases routinely notified and the number actually confirmed are shown in Table 17.14. If routine notification data had been accepted, 21 cases would have been recorded in 1969, the pattern of occurrence suggesting that smallpox had been transmitted continuously throughout the year. During the investigation of these 21 cases, as well as that of 64 other suspected cases reported by other sources, a total of 215 cases of fever with rash were identified, of which only 83 were smallpox. All occurred between January and May.

Of the 61 cases discovered in Togo during April and May 1969, all but 2 were in riverine areas, difficult of access, in the south-east near the border with Dahomey. There, resistance

to vaccination had been the greatest and, despite two intensive vaccination campaigns, only 60% of the population had vaccination scars (Table 17.15). Early in April, programme staff were notified of suspected cases by a health centre and, on investigation, they discovered 8 outbreaks with a total of 47 cases. The first of the cases had occurred 2 months before but neither these nor subsequent cases had been reported by the responsible health worker, who, as was later discovered, had vacated his post in January. With transmission apparently close to being interrupted, the President of Togo requested the army to form a *cordon sanitaire* around the areas, and police accompanied teams to lend authority to the effort; markets were closed and public gatherings forbidden. Personnel drawn from other regions vaccinated 45 420 persons in April, a figure which, by September, had grown to 248 854. The last 2 cases in this series of outbreaks occurred towards the end of April, less than 3 weeks after the initial discovery of cases. A survey in September showed that vaccinal immunity had increased from 60% to 93%.

Togo's last 2 outbreaks, numbering 6 cases in all, were discovered in May 1969 in isolated but reasonably well vaccinated fishing villages near the border with Dahomey. These were apparently the last cases of a major epidemic which had occurred throughout the area late in the preceding year.

Transmission appeared to have been interrupted in Dahomey in January 1969, but in July an infant from Dahomey was diagnosed as a smallpox patient in a dispensary in Togo near the border. Teams from the two countries converged on the area in a coordinated search and vaccination operation on both sides of the border. In all, 55 further cases occurred in Dahomey over the next 2 months but in September 1969 the last case was detected. Until March 1970 (see the section on Nigeria, above) this was thought to have been the last case in western and central Africa.

Programme staff in Togo collected data regarding the age distribution of most smallpox cases occurring between 1967 and 1969; these are presented in Table 17.16. It is of interest that each year 40-50% of all cases occurred among persons aged 15 years and over. This finding reflected the occurrence of the disease in isolated rural villages which experienced smallpox only infrequently and whose inhabitants were poorly vaccinated.

Although programmes in Dahomey and Togo had only limited resources, they began to function reasonably well after little more than a year, and only 18 months later transmission was interrupted. Resistance to vaccination in the southern areas of the countries proved to be a problem, although variolation, associated with fetish practices, was observed only once during the course of the programme.

### Mali, Niger and Upper Volta

The third of the 7 groups of countries are 3 inland states, which extend over 2.8 million square kilometres in the central part of western Africa—Mali (population in 1967,

5.3 million), Niger (population, 3.9 million), and Upper Volta (population, 4.8 million). Topographically, the area encompassed by these countries consists of desert in the north, giving way to the semi-desert areas of the Sahel and then to savanna in the south. In Upper Volta the population was evenly dispersed throughout the country, but in Mali and Niger the northern areas were very sparsely populated, virtually all of Mali's population living in the southern half of the country and 90% of Niger's being concentrated along the western and central segments of the Niger river, near the country's southern border, in a belt less than 250 kilometres wide. Thus, although both Mali and Niger were far larger than Upper Volta, the areas with a significant concentration of population in these countries were only slightly greater than in Upper Volta. As in most parts of western and central Africa, roads were few and communications difficult.

The majority of the population were sedentary agriculturalists living in villages of fewer than 1000 inhabitants. Large numbers of pastoral nomads, however, were to be found in all 3 countries, being especially numerous in Mali and Niger. They were predominantly Tuareg and Peuhl tribal people, who moved along well-defined routes seeking pasturage for their animals. During the May-October rainy season, the nomads worked on farms or congregated in pasture areas, but during the October-April dry season, they migrated over great distances. During this period, smallpox spread extensively.

OCCGE had its headquarters in Upper Volta and the country's endemic diseases control service, directed by a French military medical officer, was perhaps the best supported and most effective of such services in western Africa in 1967. In Niger, a similar service existed, but its performance was much less satisfactory. In Mali, which had ceased to receive financial support from France, the multi-purpose teams no longer functioned, having been replaced in 1962 by 2 mobile smallpox vaccination teams.

In these countries, in which health services were traditionally provided by mobile teams, there was both interest in and a structure for a large-scale combined smallpox and measles vaccination campaign. As has been described earlier, Upper Volta had, in fact, completed a national measles vaccination campaign in 1962. However, the assessment of vaccination coverage and surveillance were unknown

practices, and government officials considered them unnecessary. Moreover, views differed within each of the countries as to whether separate teams should conduct the measles and smallpox vaccination campaigns or whether they should, in some manner, be incorporated into the scope of work of multi-purpose teams. Because of these problems, there were delays in the signing of programme agreements, although all the programmes became operational by April 1967. In the end, none provided for ongoing assessment of vaccination coverage; surveillance activities, although originally intended to be conducted by national teams, became, by default, the responsibility of CDC advisers.

In Mali, a special smallpox vaccination campaign had been in progress since December 1962 with 2 teams, each composed of 15 persons, administering freeze-dried smallpox vaccine provided by the USSR and yellow fever vaccine produced in Senegal. Mali was handicapped by a lack of trained personnel, transport and petrol and requested assistance from WHO, which began to be provided in 1964; a WHO medical officer was assigned to the programme in December 1965.

A WHO team which assessed the Mali programme in February 1965 described the prospects for eradication there as "bleak" (World Health Organization, 1965b). In the campaign, vaccinators were expected to average 140 vaccinations a day, but even this modest target was not being met. At that rate of work, the WHO team estimated that it would take at least 8-10 years to complete one round of vaccination. Such vehicles as were available were old and frequently out of order,

and refrigerators did not function. The vaccine was stored at ambient temperatures of up to 50 °C, which caused it to deteriorate and the take rates to decline as a result. The vaccination campaign did not improve materially during 1965-1966, but the number of reported cases decreased significantly, reaching, in 1966, the lowest total ever recorded in Mali (Table 17.17).

With the offer of AID assistance, government health officials in Mali decided to reconstitute the multi-purpose mobile teams, 8 such teams being created to administer yellow fever vaccine, as well as smallpox and measles vaccine, and to examine and treat patients for onchocerciasis, trypanosomiasis and leprosy. The problems involved in drawing up plans and in training teams for this more complex set of activities delayed the launching of the programme. Further delays resulted from the government's insistence that each trip the CDC advisers (Dr Pascal Imperato and Mr Jay Friedman) made outside the capital should be authorized weeks in advance. Although this requirement applied to all foreign advisers at the time, it was apparent that this policy would seriously handicap the necessary training of staff and all but preclude the establishment of surveillance and containment measures. The problem was compounded by a lack of collaboration between the smallpox eradication adviser assigned by WHO and the CDC staff, which resulted in the government's receiving contradictory advice. In view of the many constraints and frustrations, senior CDC smallpox eradication staff proposed suspending assistance until the problems could be sorted

Table 17.17. Mali, Niger and Upper Volta: numbers of reported cases of smallpox and vaccinations performed, 1962-1969

Year	Mali (population, 1965: 5 105 000)		Niger (population, 1965: 3 736 000)		Upper Volta (population, 1965: 4 648 000)

<sup>2</sup>.. = data not recorded.

out. When confronted with this possibility, the government decided to give the advisers full freedom to travel; a new Chief Medical Officer, Dr Ousmane Sow, was appointed; and the WHO smallpox eradication officer completed his assignment and returned home. The campaign proceeded to gain rapid momentum. The complex logistics and problems of conducting a vaccination campaign in areas such as Mali have been described by Dr Imperato in his book, *A Wind in Africa* (Imperato, 1975).

The teams began work in areas in the eastern part of the country, in which most cases of smallpox were then being reported. The cases were mainly among nomads and in remote rural areas (Imperato et al., 1972), a distribution attributed to the great distances separating the vaccination assembly points established during the 1962-1966 campaign. Early surveys in the more accessible areas revealed that 93% of the farmers, but only 54% of the nomads, had vaccination scars. In some areas, the inhabitants of entire villages, far from the assembly points, remained unvaccinated, as were many young children and elderly persons, who could not easily walk or be carried over long distances. Assembly

points continued to be used, as in the earlier campaign, but they were more numerous, requiring the villagers to travel less far.

In April 1967, the CDC advisers began to investigate some of the outbreaks. The first were in east-central Mali, in which mass vaccination had been completed in 1965 but, as was discovered, less than half the population had a vaccination scar. Smallpox transmission, nevertheless, was not rapid, even in the season of highest incidence. In one outbreak, for example, only 71 cases were found to have occurred over a 4-month period (Imperato, 1970). As the programme moved towards the border with Upper Volta, the teams began to encounter a large number of persons who refused vaccination and found that many women and children were hidden when the teams arrived. Vaccination continued throughout the east-central area, 521 000 people being vaccinated over a 2-month period beginning in October 1967. Although programme staff had expected to find epidemic smallpox occurring widely throughout the country, only 293 cases were discovered during 1967, most of which were in areas bordering on Upper Volta, in which a mass vaccination campaign was in progress. Of the

WHO / CHEVATIER

Plate 17.13. Mass vaccination in Mali, using jet injectors.

total, 145 cases occurred in a cluster of 5 villages whose aggregate population was only 3700. Variolation was responsible for some of the cases—the only occasion on which variolation was observed in Mali.

Following the mass campaign in the endemic border areas, 2 further outbreaks, of 12 and 28 cases, were discovered in March 1968 among unvaccinated children who had been hidden from the teams (Imperato et al., 1973). Repeat vaccination in the respective villages quickly terminated the outbreaks, and for 6 months no further cases were found or notified in the entire country. It appeared that smallpox transmission in Mali had been interrupted by the time the vaccination campaign was little more than a quarter of the way towards completion.

On 6 November 1968, however, programme staff in Mali received a telegram from Upper Volta informing them that the first case in an outbreak near the border had come from a village in Mali. The Upper Volta outbreak—the last in that country—had begun in May 1968 and although 6 months had elapsed since the first case had entered Upper Volta from Mali, programme staff from the two countries agreed that a joint search should be undertaken. This began on 14 November. The village from which the initial case had come was 10 kilometres from a road and could be reached only by a narrow footpath through a mountainous rocky area. On arrival, the teams discovered that the village consisted of 8 widely separated groups of huts with a population of about 1350 people. During the vaccination campaign, which had concluded 1 year previously, the villagers had been directed to visit an assembly point 10 kilometres away, but few had done so. An outbreak had begun in late 1967 and spread progressively from one of these groups of huts to another.

Despite the fact that this was then Mali's only known focus of smallpox, the containment measures were surprisingly incomplete: only 541 villagers (40%) were vaccinated and only 16% of them were found to have vaccination scars. Pockmarks indicative of recent smallpox were observed in 65 of the 541 people examined, the last person to contract the disease having become ill in October 1968, a month before the team's arrival.

Only 1 further case was discovered in Mali, in February 1969; it occurred in a migrant tribal group believed to have been infected in

Niger. This was the last of 9 known outbreaks, comprising a total of 370 cases, which had originated among migrant Tuaregs and Peuhl nomads between 1967 and 1968, and accounting for more than three-fourths of all cases recorded in Mali (Sow, 1970).

In Upper Volta, smallpox vaccination had been a routine activity of the mobile multi-purpose teams, and the director wanted to continue this practice. He believed, correctly, that smallpox was then substantially under control and saw no reason to mount a special effort, since he did not consider eradication of the disease to be achievable. However, he decided to create special teams to administer measles vaccine, much as had been done in the 1962 campaign.

Smallpox incidence in Upper Volta had diminished greatly after 1962, as it had in Mali. Because there were comparatively few cases and responsibility for the smallpox vaccination campaign had been assumed by the endemic diseases control service, the CDC advisers, Dr Christopher D'Amanda and Mr William White, devoted substantial time to the improvement of reporting and the investigation and containment of outbreaks. In 1967 they discovered 195 cases, mainly along a north-south route used by pastoral nomads. In 1968, however, the epidemiological pattern changed. Only 100 cases were found, all of them in small villages near the border with Mali or Niger (D'Amanda, 1970). One outbreak of 19 cases in a village only 3 kilometres from the border with Niger led to a joint vaccination campaign by teams from Niger and Upper Volta. In October 1968, the last outbreak in Upper Volta was discovered by one of the multi-purpose teams in a village of 650 persons situated in a rocky mountainous area near the border with Mali. Forty cases had occurred between May and October, the first being infected in Mali; only 2 patients remained with active disease. Thorough vaccination in this and neighbouring villages quickly stopped transmission.

The concentration of cases along the frontier areas, in which health dispensaries were the most scarce, led to changes in the programme strategy in 1969. The schedule of the multi-purpose teams was altered to achieve a thorough coverage of the frontier areas, and the 604 mobile and established health units, as well as members of mobile teams giving leprosy treatment, were asked to supply weekly reports. The new system elicited many additional rumours of smallpox cases, but

transmission had ceased by then and no importations were detected.

For Niger, smallpox was a much greater problem than for Mali or Upper Volta. In all, 1023 cases were recorded in Niger in 1966 and 1187 in 1967. Until 1967, the numbers of smallpox vaccinations given by mobile teams, in proportion to population, were comparable to those in Mali, but the campaign in Niger had not achieved effective smallpox control. In part, the failure could be attributed to the high ambient temperature and the inactivation over time of improperly stored freeze-dried vaccine. This was apparent from studies conducted in early 1967 which showed primary take rates of only 20–25%. Another contributory factor was Niger's proximity to northern Nigeria. Most of the population lived within 250 kilometres of the Nigerian border, and many travellers crossed it. Mali and Upper Volta, in contrast, were at a considerable distance from the heavily endemic coastal areas of neighbouring countries.

Of special concern to the CDC advisers, Dr Donald Moore and Mr Anthony Masso, as well as to the national programme staff, were

the nomads, estimated to number about 530 000. They travelled widely throughout Niger and to neighbouring countries and were, therefore, considered to constitute a special risk in the spread of smallpox. Moreover, they were said to practise variolation when outbreaks did occur, thereby amplifying the outbreaks and increasing dissemination.

The vaccination campaign, utilizing teams devoted solely to giving smallpox and measles vaccine, began well and, by the end of 1967, 1.61 million people—equivalent to 41% of the population—had been vaccinated. A component of the programme during its first year was a special campaign aimed at vaccinating nomads, some 150 000 of whom gathered annually in a pasturage area 600 kilometres from the capital. Although the strategy was sensible, it proved to be a far more difficult endeavour than had been expected when the rains turned the few dry roads into a quagmire which could scarcely be traversed even with 4-wheel-drive vehicles. A sand storm ripped the tents and scattered the camping equipment, and the nomads sought to evade the

**Plate 17.14.** In Niger, a health worker uses the WHO diagnostic wall chart to explain the difference between smallpox and chickenpox, an important educational activity in the surveillance phase of the programme.

teams, fearing that they were also engaged in tax collection. Ultimately, as was revealed by assessment, only 45% of the population were vaccinated.

In 1967 and the early months of 1968, some outbreaks in Niger were investigated and containment vaccinations performed, but the principal effort was directed to the difficult logistics of the vaccination campaign. During the first 6 months of 1968, an additional 725 000 persons were vaccinated, following which—and coincidentally with the beginning of the seasonal rains—smallpox incidence declined sharply and did not increase again. Only 24 cases were recorded during the last 6 months of 1968 and another 28 cases in 1969. Although they were not fully documented, all the cases in 1969 are believed to have resulted from importations from Nigeria.

Despite the concern of programme staff, nomads in Niger—unlike those in Mali and Upper Volta—were found to play only a minor role in transmitting smallpox from place to place, even in the more densely populated areas. In the vast but sparsely populated northern regions of Niger, in which an estimated 150 000 nomads lived, only 1 case was discovered. That smallpox did not spread through this area was welcome but unexpected, and was probably partly due to a comparatively high level of immunity induced by vaccination as well as variolation (Masso, 1970). In a survey conducted in 1969, 38% of the nomads examined were found to have vaccination scars, but an additional 29% had the scars of variolation. Evidence of past variolation was frequently observed in different parts of Niger, and although the practice was originally believed by health staff to be important in sustaining transmission, only a single instance of recent variolation was observed—in October 1967 in a village near the Nigerian border.

The transmission of smallpox in Mali, Niger and Upper Volta was interrupted more rapidly than had been foreseen, but the problems of logistics and vaccination proved greater than expected. In Mali and Upper Volta, previous vaccination campaigns had been successful in sharply reducing the incidence of smallpox, and in less than 2 years—in November 1968—transmission was interrupted in both countries. In Niger, smallpox incidence was high at the outset of the programme, but the vaccination campaign progressed rapidly and transmission was in-

terrupted at about the same time as in the other countries.

### Guinea and Sierra Leone

The fourth of the 7 groups of countries to be discussed consists of 2 neighbouring coastal countries, Guinea and Sierra Leone. Programmes in both countries began in December 1967, nearly 12 months after the regional programme had started. As has been noted earlier in this chapter, the reason for the delay was that the CDC staff wanted to phase in activities over a 2-year period. When this decision was made, the fact was not recognized that cycles of epidemic smallpox had recurred in these countries at intervals of 10–12 years. Major epidemics had occurred in Sierra Leone in 1956–1958, and in Guinea in 1955–1957, although in the latter country nearly 3000 cases occurred only 5 years later, in 1962. In both countries, epidemic smallpox recurred early in 1967 (Table 17.18). Sierra Leone (population, 2.7 million) recorded 1697 cases and Guinea (population, 3.7 million) 1530 cases, giving incidence rates for that year which were among the highest in the world. In aggregate, the total number of cases represented nearly a 10-fold increase in incidence over 1966.

The launching of both campaigns in December 1967 coincided with the advent of the dry season—the season of highest incidence—and the beginning of the second year of the epidemic. Smallpox being a matter of much concern at the time, Guinea and Sierra Leone gave their full support to the programme and developed plans to complete the mass vaccination campaign within 16 and 24

Table 17.18. Guinea and Sierra Leone: number of reported cases of smallpox, 1960–1969

Year	Number of cases	
	Guinea	Sierra Leone
1960	176	12
1961	96	6
1962	2 948	78
1963	224	14
1964	320	90
1965	70	60
1966	56	293
1967	1 530	1 697
1968	330	1 143
1969	16	80

months, respectively. In the summer of 1968, case detection and outbreak containment were given special emphasis. Smallpox incidence declined rapidly, and the last cases were recorded in January 1969 in Guinea and in May 1969 in Sierra Leone. Benefiting from experience in the other countries of western and central Africa, these programmes were the best executed and the best documented. An account of the programme in Sierra Leone has been given by Dr Evelyn Cummings, the Chief Medical Officer, and Dr Donald Hopkins and Mr James Thornton of CDC, and their colleagues (Hopkins et al., 1971a, b, c). Guinea's programme has been described by Dr A. B. Alécaut, the director of the country's endemic diseases control service, and Dr Joel Breman, the CDC medical epidemiologist, and their colleagues (Alécaut et al., 1970; Breman, 1971; Breman et al., 1977a, b).

The population in both countries consisted primarily of sedentary farmers living in villages of less than 1000 inhabitants, most of which were not readily accessible by motor vehicle. The most densely populated part was the coastal area from Freetown, the capital of Sierra Leone, to Conakry, the capital of Guinea. In the more sparsely populated area comprising north-eastern Guinea and north-eastern Sierra Leone, cattle herders moved freely between the two countries. Work in the diamond mines of eastern Sierra Leone attracted many farmers during the dry season.

In 1967, neither country had a continuing special programme for smallpox vaccination. Vaccinations were performed by the established health units and, in Sierra Leone, by a mobile unit of the endemic diseases control service, which periodically conducted small-scale mass vaccination campaigns. Approximately 700 000 persons were reported to have been vaccinated each year in Guinea and 300 000 in Sierra Leone. In Guinea, freeze-dried vaccine from Switzerland and the USSR began to be used in the early 1960s. Sierra Leone, like Nigeria, employed the thermolabile lanolinated vaccine purchased from the United Kingdom or Nigeria. Surveys in Sierra Leone when the programme began revealed vaccination scars in only 26% of those under 15 years of age and in 60% of older persons. Overall, almost half the population of Sierra Leone was considered to be susceptible to smallpox. Comparable data from Guinea are not available.

Smallpox incidence began to increase in Sierra Leone in 1966 (Table 17.18); in 1967

the disease became endemic throughout the country, the eastern areas being the most affected. In Guinea, the incidence started to increase a year later, the most heavily afflicted areas being the coastal districts bordering on Sierra Leone (Fig. 17.7.). Because of the spreading epidemic, an emergency mass campaign was conducted in Conakry in February and March 1967, during which 180 000 of the city's 250 000 inhabitants were vaccinated.

In Guinea, the AID-supported vaccination campaign began in December 1967, utilizing, as supervisory personnel, senior staff of the former endemic diseases control service, which, by 1967, had ceased to function owing to a lack of vehicles and of funds for petrol and equipment. Vaccination was conducted by 8 mobile teams of 6 persons each: a team leader, 2 vaccinators, a recorder, a driver and an "advance man". The last-named visited leaders of the well-organized political party in each area and village prior to the team's arrival, in order to acquaint them with the programme and to obtain their support. To simplify the logistics of providing supplies, all teams worked together in a given region of the country, vaccinating at assembly points situated so that villagers had to walk no more than 2-3 kilometres. Local costs, which amounted to US\$10 000 per annum, were covered by WHO.

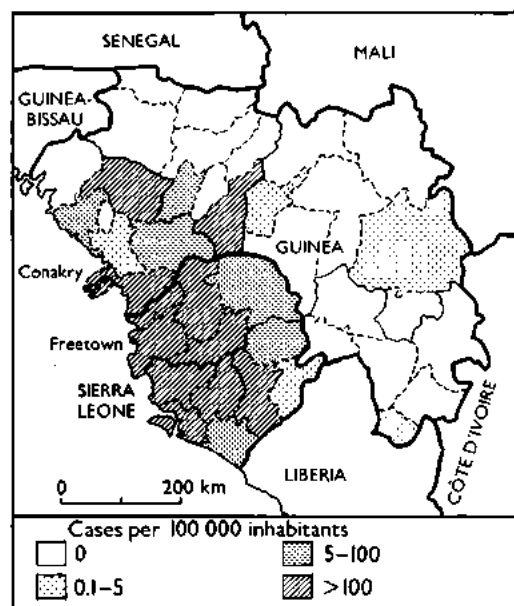

Fig. 17.7. Guinea and Sierra Leone: smallpox incidence, by province, 1967.

From the beginning, vaccination coverage in Guinea was carefully assessed. Two methods were used. The first, performed when the teams were working in the village, consisted simply in comparing the numbers vaccinated with the population census. If the numbers vaccinated seemed to be low, local party officials were asked to search for those who had been missed, and send them for vaccination. Where vaccination coverage was particularly low, a special team was assigned to conduct repeat mass vaccination and vaccine was sometimes left with regional officials, who were asked to vaccinate the people who had been missed.

The second form of assessment, conducted a week later by a senior technical officer of the programme and an assistant, utilized the modified cluster sample technique devised by Dr Ralph Henderson (Henderson et al., 1973); this required the examination of a number of persons sufficient to ensure, with 95% confidence, that the results obtained were within 10% of the true value. Although this was a more sophisticated survey method than that routinely employed in other programmes, it was well executed. As the programme progressed, it was found that the results of the two types of assessment usually corresponded well, due primarily to close supervision of teams and the availability of unusually accurate census data.

With the active cooperation of party leaders, the levels of vaccinal immunity achieved usually exceeded 80% and more often 90%. The teams themselves averaged 2000 smallpox vaccinations a day and, in addition, provided measles vaccination to all children between 6 months and 4 years of age.

From January to October 1968, the end of the rainy season, the residents of Conakry and of all districts bordering on Sierra Leone were systematically vaccinated (Fig. 17.8). These areas included most parts of the country then known to be infected with smallpox.

The investigation and containment of outbreaks began within months of the start of the mass vaccination campaign. In June 1968, a special surveillance team was assigned this responsibility and asked to make a village-by-village search for cases in high-risk areas. By then, owing to the decrease in incidence during the rainy season and the high levels of vaccinal immunity in previously infected areas, smallpox had all but disappeared. From July 1968 to the end of January 1969, only 8 outbreaks, with a total of 75 cases, were

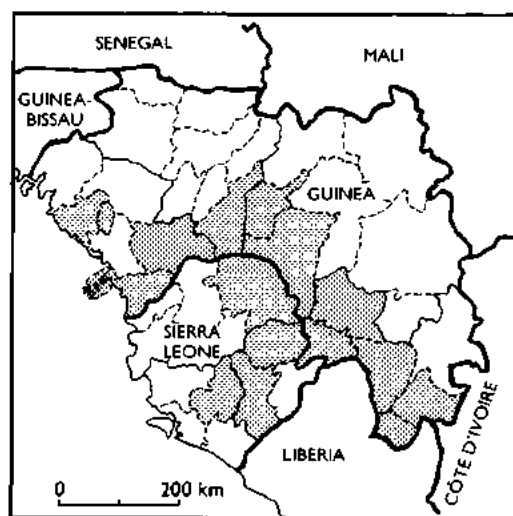

Fig. 17.8. Guinea and Sierra Leone: areas (shaded) in which mass vaccination was completed before the end of the rainy season, October 1968.

discovered, almost all in villages of less than 500 inhabitants. All were in western Guinea, near the border with Sierra Leone, and 5 of the 8 were thought to have originated in that country. In each instance, information regarding the source of infection was cabled promptly to Sierra Leone. The last known case in Guinea was reported and investigated in January 1969, though it actually occurred in December 1968.

The first phase of the systematic vaccination campaign continued until June 1969. In all, 3.1 million smallpox vaccinations were given during the 18-month period, another 2.6 million during a subsequent 2-year cycle, and a further 2 million in a third 2-year vaccination cycle. Meanwhile, weekly reports from each of the 29 regions were being received with increasing regularity. In 1968, 33% of the expected reports were received—a proportion which increased to 60% in 1969, and to 87% in 1970.

The smallpox problem in Sierra Leone differed from that in Guinea in that the disease was widespread throughout the country. The campaign, which began in January 1968, utilized the staff of the endemic diseases control service, which had previously been responsible for 43 treatment centres for yaws and trypanosomiasis. Six teams performed the vaccinations and one the assessment. The composition of the teams and their methods of work were similar to the system operating in Guinea. Priority was given to

eastern Sierra Leone, in which smallpox incidence was the highest, presumably because of a large population turnover associated with diamond mining and the migration of cattle herders. Because of the epidemics, attention was initially concentrated on vaccinating as widely and as rapidly as possible before the end of the rainy season in 1968 and the commencement of the expected seasonal increase early in 1969.

The help of tribal chiefs in the 146 chiefdoms was necessary to obtain the cooperation of villagers. Although the chiefs were generally receptive, they proved to be less effective than Guinea's political party leaders. Efforts were made to achieve a vaccination coverage of 80% or more in all areas, but assessment showed that it was usually no greater than 75%.

A few outbreaks were investigated between January and August 1968, but a concerted effort to investigate and to contain all reported outbreaks did not begin until August, when the regional "eradication escalation" activity commenced. Vaccination teams were assigned in rotation to this duty. As in Guinea and in other countries at this time, outbreak containment consisted primarily of 1-2 days of intensive vaccination in the infected village, in neighbouring villages and in nearby

markets. Patients were isolated in their houses, a traditional practice in most of this part of Africa. Nearly all the cases (94.5%) in Sierra Leone occurred in villages of less than 1000 inhabitants and although containment measures were less rigorous than in the later phases of the Intensified Smallpox Eradication Programme, most outbreaks ended quickly. Studies by the programme staff showed that no secondary cases occurred in villages in which coverage was greater than 80%, and 1-9 secondary cases in those in which vaccinal immunity was less than 70%.

An unusual feature of smallpox transmission in Sierra Leone was the occurrence of outbreaks associated with special funeral ceremonies for smallpox victims. In two documented outbreaks (Hopkins et al., 1971c), cases occurred among members of secret societies who washed the corpse of the smallpox victim and among others who attended special funeral services. One of the outbreaks gave rise to 33 cases among contacts at the funeral and an additional 97 cases due to further spread; the other resulted in 10 contact cases and 2 cases due to secondary spread. While secret societies were prevalent throughout western Africa, and other such outbreaks were believed to have occurred in Sierra Leone, these were the only ones which could be documented.

From August 1968 onwards, the number of cases in Sierra Leone decreased steadily and from January to the end of April 1969, only 12 outbreaks, with a total of 80 cases, were found, all but one situated in coastal areas in which mass vaccination had not yet been conducted. On 5 April, the last case occurred, in Freetown; it was not officially reported until May and the source of infection was not discovered.

An important contribution to the success of the programme was the monthly publication of a mimeographed bulletin, *The Eradicator*, which was distributed widely to programme staff, medical officers, dispensers, civil officials, paramount chiefs and other interested persons. It reported on the programme's progress, paid tribute to effective health workers and local officials and announced the schedule of activities for the coming month. When the intensified surveillance programme began in August 1968, the bulletin served to stimulate reporting throughout the country.

Data on the age distribution of cases and case-fatality rates in Guinea and Sierra Leone

1973

**Plate 17.15.** Donald R. Hopkins (b. 1941), a CDC epidemiologist, served as the senior adviser to the programme in Sierra Leone. Although the incidence of smallpox in Sierra Leone was among the highest in the world in 1967, it was possible to interrupt transmission in only 16 months. Hopkins later wrote a history of smallpox, *Princes and Peasants*.

Table 17.19. Guinea and Sierra Leone: number of cases of and deaths from smallpox and case-fatality rate, by age, 1968-1969

Age group (years)	Guinea <sup>a</sup>			Sierra Leone <sup>a</sup>		
	Number of cases	Number of deaths	Case-fatality rate (%)	Number of cases	Number of deaths	Case-fatality rate (%)

Total	305	23	7.5	1 180	131	11

<sup>a</sup> Data are not available for 41 cases in Guinea and 43 cases in Sierra Leone; in addition, the age distribution of 85 cases in Sierra Leone is unknown though their outcome was recorded.

were more complete than in most national programmes, and it is pertinent to include them here, since they are probably representative of the situation in other countries of the region (Table 17.19).

In proportion to population, cases were more numerous among children than adults, but there was, nevertheless, an unusually large percentage of adult cases in what were considered to be endemic countries. Most of the cases, however, occurred in rural areas, in many of which smallpox had not been present for several decades. The low levels of vaccinal immunity in these areas, coupled with the infrequency of variolation, ensured the presence of many susceptible adults when outbreaks occurred. Because of the nature of data collection, the case-fatality rates probably understate the severity of the disease. Since in most of the fatal cases of smallpox, the patients did not die until the second or third week of illness, some who were acutely ill at the time of outbreak investigation may have died later but their deaths were not recorded. An overall case-fatality rate of perhaps 10-15%, depending on the age distribution of cases, would probably be more correct.

The programmes covering the comparatively small populations of Guinea and Sierra Leone, both highly endemic at the start, are of interest because of the rapidity with which they succeeded in interrupting transmission. Guinea's last case occurred only 12 months, and Sierra Leone's only 16 months, after the inception of their respective programmes. This achievement in two countries which were so lacking in health services, transport, and communications greatly encouraged regional and global smallpox eradication programme staff and, to some extent,

generated an unwarranted confidence that comparable successes could be achieved as readily in other parts of the world.

### Côte d'Ivoire, Ghana and Liberia

In the adjoining countries of Côte d'Ivoire, Ghana and Liberia, smallpox had largely been brought under control by 1967; Côte d'Ivoire, in fact, had succeeded in interrupting transmission (Table 17.20). Each had achieved this status in a different manner: Côte d'Ivoire by mass vaccination, with little external assistance; Liberia through a mass vaccination campaign supported by a private voluntary organization; and Ghana by a remarkably effective programme of surveillance and containment.

Ghana is of special interest, being one of the few countries in which an effective programme of case investigation and outbreak control all but interrupted smallpox transmission despite a comparatively low level of vaccinal immunity in the population

Table 17.20. Côte d'Ivoire, Ghana and Liberia: number of reported cases of smallpox, 1961-1968

Year	Number of cases		
	Côte d'Ivoire	Ghana	Liberia

<sup>a</sup> Imported from Upper Volta.

<sup>b</sup> Imported from Togo.

and the use of a thermolabile smallpox vaccine. Ghana was the second most heavily populated country in the western and central African region (population in 1967, 8.1 million), and in the 1950s and 1960s had one of the best-organized health services and networks of all-weather roads. A moderately extensive morbidity reporting system had been established, and a compulsory mortality registration scheme covered approximately half the population. Between 500 000 and 1 million persons were vaccinated annually in hospitals, health centres and health posts and by mobile rural health service teams (originally called medical field units). The thermolabile lanolinated vaccine produced in the United Kingdom was used exclusively until 1964, when freeze-dried vaccine began to be purchased from Switzerland. However, on the basis of field observations by a WHO adviser in 1965, and outbreak investigations in 1967, it can be assumed that overall vaccinal immunity was probably not greater than 50% when the programme began. Despite this, no more than 251 cases had been notified in any year since 1953—that is, during a period when many countries in western and central Africa with smaller populations reported 1000 or more cases every year. The explanation can be found in the existence of a corps of well-trained sanitarians who took special care to keep the vaccine refrigerated, investigated all outbreaks, isolated patients in a hospital or in separate quarters, vaccinated those living in the area and recorded the daily temperature of household contacts in order to detect additional cases as early as possible. Only 7 cases of smallpox were notified in 1965 and 13 in 1966.

The mass vaccination campaign began in February 1967 in the capital, Accra, utilizing the mobile health service teams to give both smallpox and measles vaccine. At the same time, senior Ghanaian programme staff, Dr Frank Grant and Dr V. de Sario, with the CDC advisers Dr Challenor, Dr David Melchinger and Mr James Lewis worked with local sanitarians in the investigation and containment of outbreaks. In all, 17 outbreaks, with 114 cases, were found in 1967. Two of these, with a total of 21 cases, were in Accra and affected only 7 households in an area populated by immigrants from Togo; 5 others, with 27 cases, were in southern Ghana, the Accra outbreaks being the source of one of them and Nigeria another; 10 outbreaks, with 66 cases, occurred in a cluster of small villages

within a few kilometres of the point where the borders of Ghana, Togo and Upper Volta meet (WHO/SE/69.8, de Sario). The last group of outbreaks occurred in a tribal area in which no cases had been seen for 6 years but in which smallpox was well recognized by its name *naba*, which means "the chief of all the other diseases". A source of infection in Togo or Upper Volta was suspected but not proved. Although the sources of infection could not be traced for all outbreaks, it is apparent that there was little endemic disease and few chains of transmission. During 1968, 24 additional cases in 6 outbreaks were discovered, all of which could be traced to importations from Togo, 2 of the outbreaks occurring very near the border, while the others were at a distance of more than 100 kilometres from it (Grant, 1970).

The mass vaccination campaign progressed steadily but more slowly than in most other countries of the region, being completed in 1970, 4 years after it had begun. Coverage levels, based on concurrent assessment, were consistently over 90%.

In Côte d'Ivoire (population in 1967, 4.9 million), smallpox had been an important problem in the early 1960s, 4656 cases having been reported in 1961. In August of that year, the government decided to embark on a special 3-year mass vaccination campaign using a freeze-dried vaccine produced in France and 5 mobile teams comprising 50 health staff. The responsibility for its execution was entrusted to the Institute of Hygiene in Abidjan and its director, Médecin-Colonel Gaston Binson. During the next 3 years, 3.6 million persons were vaccinated; a repeat 3-year campaign, lasting from 1964 to 1966, succeeded in vaccinating another 3.7 million. Smallpox incidence fell precipitously and by 1965, only 27 cases were notified, followed by 10 cases in 1966.

When assistance was provided by the USA, the government decided to undertake a third national smallpox vaccination campaign under the same leadership as before; other teams from the Ministry of Health, working independently, administered measles vaccine. The smallpox vaccination campaign differed somewhat from those in other countries in that the vaccine was administered by scarification rather than by jet injector. Dr Binson saw little virtue in speeding up the rate of vaccination by using the jet injector, since this was offset by the time-consuming process of preparing for each person vaccinated a signed

T. D. M. BINSON

**Plate 17.16.** Headquarters of the national smallpox eradication programme at Abidjan, Côte d'Ivoire.

personal vaccination certificate giving the individual's name, the date of vaccination and the batch number of vaccine used. The preparation of a vaccination certificate was traditional in Côte d'Ivoire, as in many of the other francophone countries and, while most countries soon abandoned the practice or simply distributed certificates without the holder's name inscribed, the traditional approach continued to be used in Côte d'Ivoire. Assessment of coverage was not performed. In November 1969, at the conclusion of the third national mass smallpox vaccination campaign, measles vaccination teams were merged with the smallpox teams, the practice of issuing vaccination certificates was abandoned and jet injectors began to be used for both antigens.

After the regional programme had commenced, only 2 cases of smallpox were discovered in Côte d'Ivoire, in March 1967, both of which were importations from Upper Volta. The cases did not appear in the official records, however, until 2 years later; the director of the programme, proud of its accomplishments, believed that the country's record should not be blemished by 2 cases for which he did not feel responsible.

Liberia (population in 1967, 1.3 million), which abutted on Côte d'Ivoire in the west, reported more than 1000 cases in 1961, and the following year began a smallpox vaccination campaign. It was directed by a religious organization called Brother's Brother, which undertook mass vaccination through-

out the accessible, populated areas (Bryant, 1968). Over a 5-month period, some 775 000 vaccinations were reported to have been given, using jet injectors of a different type from those subsequently employed by CDC, and a freeze-dried vaccine, which was diluted approximately 15-fold owing to a lack of supplies. Neither vaccination take rates nor coverage was assessed.

After the 1-year mass campaign, WHO provided an adviser, Arita, and enough freeze-dried vaccine to permit a more systematic programme which utilized undiluted vaccine administered by scarification. That this was needed became apparent when Arita found that only 60–70% of persons had had successful primary vaccinations when vaccinated in accordance with the procedure used by the Brother's Brother group. Progress in the WHO-supported programme was slow, but smallpox incidence continued to fall. Although the number of reported smallpox cases had averaged more than 1000 per annum from 1958 to 1962, only 325 cases were reported after the first mass campaign in 1962. The figure dropped to only 40 cases by 1965, to 32 by 1966 and to 6 by 1967.

The AID-supported campaign, which began early in 1968, progressed little more satisfactorily than had the campaigns in 1962–1967. Even with 7 vaccination teams, nearly 4 years were required to complete the operation. Assessment was seldom conducted and reporting remained almost as unsatisfactory at the conclusion of the programme as at the beginning. Nevertheless, a system which had notified hundreds of cases in previous years reported only 5 cases in 1968, all of which occurred during the first 3 months of that year. Nothing is known of these cases, since no reports of cases were investigated until April 1968. Some—perhaps all—may have been erroneously diagnosed, or they may have been importations. No further cases of smallpox were discovered by vaccination teams as they advanced systematically across the country, but in 1970 they did detect the first cases of human monkeypox outside Zaïre (see Chapter 29).

### The Gambia, Mauritania and Senegal

The Gambia, Mauritania and Senegal, 3 contiguous countries comprising the westernmost part of the region, recorded no cases of smallpox after 1966 (Table 17.21). The

Table 17.21. Gambia, Mauritania, Senegal: number of reported cases of smallpox, 1961-1967

Year	Number of cases		
	Gambia	Mauritania	Senegal
1961	12	12	201
1962	4	40	232
1963	52	0	231
1964	6	0	2
1965	6	2	2
1966	3	76	0
1967	0	0	0

cessation of reported smallpox that year followed many years of effective control measures, especially in Senegal, which accounted for 70% of the area's population (in 1967) of 5.3 million and which was economically the most developed. The Gambia, a strip of land 16 kilometres wide and 320 kilometres long, entirely surrounded, except for the coastal section, by Senegal, had a population of 438 000, which moved freely back and forth across the border. Not surprisingly, its experience with smallpox reflected that of Senegal. Mauritania, although 6 times larger than Senegal, was mostly desert. Because its predominantly nomadic population of 1.2 million was widely dispersed throughout the country, the transmission of smallpox was not easily sustained. After 1962, Mauritania reported 78 cases of smallpox—2 in 1965 and 76 in 1966. Government reports, however, note that the 1966 cases, all in a confined area, had never been confirmed by a physician and, in retrospect, chickenpox was thought to have been a more probable diagnosis.

In Senegal, the endemic diseases control service had been in operation for many years and had a personnel of 292 in 1967. With a reasonably extensive network of all-weather roads, the multi-purpose mobile teams were able to move comparatively easily throughout the country. Vaccinations, equivalent in number to about 20% of the population, were administered annually. Since the early 1960s, a good-quality freeze-dried vaccine produced in France had been used, a factor which undoubtedly contributed to the interruption of smallpox transmission. No surveys were performed either before or during the programme to assess the level of vaccinal immunity, but it was believed to be reasonably high. For the AID-supported programme, the government decided that the supplies and equipment provided should be utilized by its mobile teams, which endeavoured to visit all

villages once every 3 years. During the first 3 years of the programme, 2.6 million smallpox vaccinations were performed. No cases of smallpox were discovered.

In the Gambia, some 50 000-75 000 smallpox vaccinations had been administered annually at health centres and dispensaries, using lanolinated vaccine produced in Nigeria. Few of the health units, however, had refrigeration equipment; supplies of vaccine were distributed monthly and kept in wet cotton until used. Mass vaccination had been conducted only once during the preceding decade—in a localized area in 1963, when an outbreak of 52 cases occurred. The proportion of successful vaccinations is unknown, but it was probably not high, as the method of storage would not have preserved the thermolabile vaccine for more than a few days. Despite the presumably low levels of vaccinal immunity and the fact that 10% of the population was migratory, few cases of smallpox were recorded, the immune barrier provided by Senegal undoubtedly playing an important role in protecting the Gambia.

With assistance provided by the USA for smallpox and measles vaccination, 3 mobile teams were created, each consisting of 2 vaccinators, a tally clerk and a driver; a health superintendent, Mr Kebba A. M. Sanneh, supervised field activities. The mass vaccination campaign began in June 1967 and was completed in 10 months (167 working days), during which 350 000 people were vaccinated against smallpox and 81 000 against measles, an average of 2580 vaccinations a day. This far surpassed the expected average of 1500 vaccinations a day (see box). The continuing programme of maintenance vaccination was no less successful. Concurrent assessment regularly showed coverage rates of more than 90%, which were sufficiently high to interrupt measles transmission for more than 2 years. No cases of smallpox were discovered after the programme had begun.

Mauritania presented a set of problems quite different from those encountered either in the Gambia or in Senegal. Like Senegal and other former French colonies, Mauritania had had an endemic diseases control service, which consisted of 7 mobile teams, each composed of 5 health workers. About 125 000 people were being vaccinated annually against smallpox with a freeze-dried vaccine produced in France. However, in 1962, most senior staff of the service left Mauritania, and thereafter team activities diminished sharply,

### Factors in the Success of the Programme in the Gambia

In a detailed paper (unpublished), the Gambian field supervisor, Mr Kebba A. M. Sanneh, enumerated the factors which he considered to be of importance in the success of the programme.

*Training:* The field supervisor was trained first and actively participated in training the teams, all of whose members (vaccinators, recorders and drivers) were trained together. This created a special team spirit. Included in the training were 5 stand-by vaccinators who could replace any who became ill. After several days of classroom training, a 3-day field exercise was conducted in a large village to work out practical problems.

*Publicity and scheduling:* Before the programme began, it was given wide publicity through the local press and radio, and through letters to all medical and health personnel, as well as to Divisional Commissioners, and through them to district chiefs. In each district, the field supervisor met each *seyfo* (chief) to discuss the programme and to obtain a list of all villages and hamlets. The *seyfo* was asked to inform each *alkalo* (village head) of the programme and assign a "badge messenger" (a type of policeman) to work with the teams. One day before the teams vaccinated in a village (the population of as many as 20 villages were vaccinated each day), a team member met the *alkalo* and requested him to ask each family head to bring his family to the vaccination assembly point. The field supervisor was given wide latitude in planning the programme, but once a village had been informed that the teams would be present on the following day, every effort was made to reach it even if this meant working for 12 hours or more.

*Support of teams:* Team morale was enhanced by support given to them by headquarters staff and other government personnel. If transport was sent on a Sunday to obtain vaccine and petrol, these would be supplied, although Sunday was not a normal working day. In addition, teams were paid promptly whenever they returned to the capital. They were given priority at ferries by Marine Department personnel, and priority in vehicle repair by the Public Works Department. The CDC advisers, Dr Thomas Drake and Mr Robert Helmholz, gave help wherever this was required, sharing with the teams the hardships of field living conditions.

*Local customs:* Public support was actively sought but no compulsion was used and no attempt was made, at any time, to foreshorten the traditional greetings required in the Gambia before any matter could be taken up for discussion. Where teams encountered the initiation ceremonies for circumcision, which necessitated the isolation of the boys and girls concerned from others in the village, the boys were vaccinated "in the bush", and the girls were vaccinated privately in a compound.

With good support from local government and villagers alike, the morale and enthusiasm of the teams remained high, permitting a programme scheduled to last 260 working days to be completed in 167 days, with an independently assessed rate of coverage of more than 90%.

only penicillin and aspirin being distributed during the period 1962-1967.

With the provision of assistance from the USA, it was decided to reconstitute the endemic diseases control service and to add smallpox and measles vaccination to its tasks. For ease of supervision it was decided that the teams would work in two separate groups, progressing from one region to the next, rather than assigning one team to each of 6 regions. However, in 1967, following the outbreak of hostilities between Egypt and

Israel, Mauritania severed diplomatic relations with the USA. The United States adviser left the country and field activities ceased after only one week, not to be resumed until 1969.

In March 1968, Dr Mayer, the WHO intercountry smallpox adviser for western Africa, visited Mauritania and, with government officials, developed a plan of operations which provided for the assignment of a WHO medical officer and an operations officer, as well as a vehicle, some items of equipment

and funds to cover local costs. The USA agreed to provide vaccines and other supplies and equipment, using OCCGE as an intermediary. The arrangement was similar to that which was devised to support the programme in the Congo.

At government insistence, two basic changes were made in the original plan: BCG vaccine (provided by UNICEF) would also be administered, and the teams would work simultaneously in 6 rather than 2 regions. In a country of 1.2 million square kilometres with few, poorly maintained roads, the dispersal of teams created difficulties in communication as well as in supervision and supply. Air transport was of little help since scheduled weekly flights served only a few of the larger towns and were frequently cancelled owing to the breakdown of equipment and to sandstorms.

Dr Mayer moved from Liberia to Mauritania in May 1968 and shortly thereafter conducted a scar survey among village children in the north of the country. Vaccinal immunity was found to be poor: among the children up to 14 years old only 45% had vaccination scars and these were almost all in the 5-14-year-olds. After 7 months of preparation, pilot field activities were resumed in January 1969, and full operations commenced in April. The programme progressed slowly, owing to difficulties in supervision and supply and to mechanical problems with vehicles. In 1969, 426 000 smallpox vaccinations were given and about one-fourth this number of measles and BCG vaccinations. In 1970, the number of vaccinations decreased by half and remained at about this level until June 1976, when the programme came to an end. However, no cases of smallpox were detected after 1966.

Although the need for smallpox vaccination in the 3 countries was questionable, since all of them had remained free of smallpox after 1966, the campaigns also provided measles vaccination and the vaccinators, in their systematic travels through the countries, were able to ensure that no foci of smallpox had been missed.

**The OCEAC Countries: Cameroon,  
Central African Republic, Chad, the  
Congo and Gabon**

Of the last group of countries to be dealt with in this chapter, all were members of

OCEAC, then directed by Médecin-Colonel Labusquière. The 5 countries (population in 1967, 13.7 million) comprised an area of almost 3 million square kilometres, which, until 1960, had been known as French Equatorial Africa. In the provision of health services, each country relied primarily on the well-established multi-purpose mobile teams of the endemic diseases control service, directed by French medical advisers who were usually military officers. The programmes in these countries all followed the same pattern, which had been agreed on in the meetings of OCEAC.

The method of operation has been described by Dr J. M. Roux, the Chief Medical Officer of Chad (Roux, 1970). A typical team consisted of 12 male nurses, 2 drivers with vehicles and 2 labourers. They administered smallpox, BCG and yellow fever vaccines; examined each person for leprosy and trypanosomiasis as well as other common endemic diseases; conducted simple routine tests on specimens of blood, faeces and urine; and prescribed appropriate treatment. For every individual examined, a special certificate documenting each procedure was prepared and retained by the person concerned. Two or three years were required for the teams to visit all parts of the country.

A freeze-dried smallpox vaccine of good quality, produced in France, began to be used

**Plate 17.17.** A health worker in Gabon repairs a jet injector. Jet injectors made it possible to vaccinate large numbers of people very quickly, but they frequently malfunctioned and their daily maintenance was essential.

Table 17.22. OCEAC countries: number of reported cases of smallpox, 1961-1969

Year	Number of cases				
	Cameroon	Central African Republic	Chad	Congo	Gabon
1961	1 145	0	502	23	0
1962	743	57	769	1 254	1
1963	135	3	10	1 476	111
1964	88	0	5	198	49
1965	28	0	73	89	1
1966	2	0	0	0	0
1967	119	0	86	0	0
1968	37	0	5	0	0
1969	3	0	0	0	0

in the early 1960s, and soon thereafter the number of reported cases of smallpox declined sharply, only 2 cases being recorded in the 5 countries in 1966 (Table 17.22).

In the initial planning for the regional programme, CDC staff had not been fully aware of the scope and extent of activities already being carried out in these countries, and had envisaged the need to create special teams for measles and smallpox vaccination such as had been done during the earlier AID-supported measles vaccination campaigns. However, OCEAC and government officials decided to incorporate the new vaccination activities into the work of the multi-purpose mobile teams, and to utilize the vehicles and equipment to strengthen existing efforts. Although this was advantageous to the execution of the vaccination campaign, the prescribed operations provided for neither concurrent assessment of the work by sample surveys nor a surveillance team to investigate suspected cases of smallpox.

OCEAC officials decided that the provision of separate assessment teams would be too costly and that it was basically unnecessary, since assessment in the OCEAC countries was conventionally done by the vaccination teams, who compared the numbers vaccinated with the estimated population in the area served. In most countries, such assessments proved misleading, partly because of inaccurate census data, but the OCEAC programmes were generally well conducted, and independent assessments, when performed, usually revealed that at least 80% and often more than 90% of the population had vaccination scars. By late 1969 and early 1970, the total numbers of smallpox vaccinations administered in each country during the course of the regional programme were al-

most equivalent to or exceeded the estimated population.

The investigation of suspected cases was generally undertaken by the CDC advisers, with assistance from local officials. After 1966, all smallpox cases in the OCEAC countries were discovered in Cameroon and Chad, in areas bordering on Nigeria. The outbreaks in Chad were traced to importations from Nigeria, as were most of those in Cameroon.

In Cameroon, during 1967-1969, 21 outbreaks, with 159 cases, were detected among tribal peoples who lived in widely scattered settlements in the rugged Mandara mountains adjacent to Nigeria. The villagers frequently crossed into Nigeria and some, in fact, maintained houses in both countries in order to escape taxes. Many villagers resisted vaccination, and because of the difficult terrain, the multi-purpose teams had not vaccinated extensively throughout the region. When surveys showed that 40% of the inhabitants had never been vaccinated, special smallpox vaccination campaigns were conducted in 1967 throughout the area, primarily in the crowded market-places. By March 1968, the last of the large outbreaks had been contained (Delas, 1970). Over the next year, however, 9 additional outbreaks of 1-7 cases occurred among visitors to Nigeria, then still heavily endemic and in which neither vaccination nor surveillance had yet begun.

The outbreaks in Chad occurred among villagers living on thousands of floating islands on Lake Chad, a shallow lake some 250 kilometres long and 25-100 kilometres wide. The islands, inhabited by fishermen, consisted of matted networks of papyrus reeds and other weeds, which often drifted for miles over the surface of the lake. Cases were reported from the area by a missionary physician in June 1967—the first cases known to have occurred in the lake area for more than 2 years. To investigate the outbreak, Dr Bernard Lourie, the CDC adviser, chartered an aeroplane with pontoons, and using a medical service boat and 4-wheel-drive vehicles, he and Chadian staff eventually identified more than 100 cases, not all of which were officially reported. The first had occurred in April among fishermen returning from Nigeria. Smallpox then spread from one small village to another in an area in which only 20-30% of the population bore the scars of vaccination. A special vaccination campaign was conducted in markets and villages

throughout the area. The floating islands presented a special problem, because when pressure was exerted on the pedal of the jet injectors, they tended to sink through the surface. The difficulty was solved by laying mats on the island. In all, some 80 000 people were vaccinated in an area thought to have a population of about 150 000. Transmission was interrupted within a matter of weeks, although importations resulted in 5 further cases in 1968.

Throughout the OCEAC countries, roads were few, the distances were great and communications were limited. Secessionist groups, who were active throughout the central and northern parts of Chad, compounded the problems there and taxed the skills of the able director of the mobile disease control service, Dr Pierre Ziegler. Rebel groups, in fact, ambushed a team, killing a labourer, wounding a driver and setting fire to one of the vehicles. Efforts to contact the secessionists to ensure safe passage proved futile, since the different groups acted independently and assurances provided by one leader did not obligate others. Accordingly, vaccination in these areas had to be restricted to the major towns and cities which had military garrisons. Neither surveillance nor vaccination was possible in rural areas of the north, but the population was sparse there, and smallpox transmission did not persist as it did under similar conditions in the Ethiopian Ogaden in 1975-1976.

## CONCLUSIONS

The elimination of smallpox in 1970—little more than 3 years after the inception of the Intensified Smallpox Eradication Programme—from the vast region of western and central Africa provided enormous encouragement to the remaining endemic countries. The fact that many countries of the region were among the world's poorest, with the least developed infrastructures of health, transport and communication, increased confidence that global eradication could eventually be accomplished. The valuable early insights into the epidemiology of smallpox and the methods for its control were no less important. Subsequently, the experience acquired by both national and CDC staff was to prove invaluable when many of them served with programmes in other parts of the world.

The regional programme was also important in that the USA provided sufficient support to make eradication feasible in this vast region; WHO did not then have resources of this magnitude available for programmes in other endemic areas. The fact that CDC staff assumed full responsibility for technical assistance permitted WHO Headquarters staff to direct their efforts and attention elsewhere. Indeed, in view of the formidable administrative problems that WHO encountered in implementing smallpox eradication programmes in other countries of Africa, it is problematic whether eradication in Africa could have been achieved without this support. At the same time, WHO's own modest but vital contribution to many of the countries by meeting the "local costs" of items such as petrol and vehicle maintenance and repair must be acknowledged.
